# **Decision Support for Enhanced Oil Recovery Projects**

**by**

**Panos Andonyadis, B.S.E**

**Thesis**

Presented to the Faculty of the Graduate School of

The University of Texas at Austin

in Partial Fulfillment

of the Requirements

for the Degree of

**Master of Science in Engineering**

**The University of Texas at Austin**

**August 2010**

## **Dedication**

To my parents, Manol and Sula.

## **Acknowledgements**

I would like to extend my gratitude to my advisor, Dr. Robert B. Gilbert, for his guidance and support throughout my graduate studies. I am also appreciative for the support and assistance from Dr. Larry Lake. My family's encouragement and unconditional support gave me the necessary strength for completing my studies. In particular my father's mentorship provided with me with the motivation to work through all obstacles.

I would like to extend my gratitude and thanks for the financial support from the Center for Petroleum Asset Risk Management, Chevron, and the University of Texas.

## **Abstract**

### **Decision Support for Enhanced Oil Recovery Projects**

Panos Andonyadis, M.S.E

The University of Texas at Austin, 2010

Supervisor: Robert B. Gilbert

Recently, oil prices and oil demand are rising and are projected to continue to rise over the long term. These trends create great potential for enhanced oil recovery methods that could improve the recovery efficiency of reservoirs all over the world. The greatest challenges for enhanced oil recovery involve the technical uncertainty with design and performance, and the high financial risk. Pilot tests can help mitigate the risk associated with such projects; however, there is a question about the value of information from the tests. Decision support can provide information about the value of an enhanced oil recovery project, which can assist with alleviating financial risk and create more potential opportunities for the technology.

The first objective of this study is to create a new simplified method for modeling oil production histories of enhanced oil recovery methods. The method is designed to satisfy three criteria: 1) it allows for quick simulations based on only a few physically

meaningful input parameters; 2) it can create almost any potential type of realistic production history that may be realized during a project; and 3) it applies to all non-thermal enhanced oil recovery methods, including surfactant-polymer, alkali-surfactant-polymer, and CO<sub>2</sub> floods. The developed method is capable of creating realistic curves with only four unique parameters.

The second objective is to evaluate the predictive method against data from pilot and field scale projects. The evaluations demonstrate that the method can fit most realistic production histories as well as provided ranges for the input parameters. A sensitivity analysis is also performed to assist with determining how all of the parameters involved with the predictive method and the economic model influence the forecasted value for a project. The analysis suggests that the price of oil, change in oil saturation, and the size of the reservoir are the most influential parameters.

The final objective is to establish a method for a decision analysis that determines the value of information of a pilot for enhanced oil recovery. The analysis uses the predictive method and economic model for determining economic utilities for every potential outcome. It uses a decision-based method to ensure that the non-informative prior probability distributions have an unbiased, consistent, and rational starting point. A simple example demonstrating the process is discussed and it is used to show that a pilot test provides some valuable information when there is minimal prior information.

For future work it is recommended that more evaluations are performed, the decision analysis is expanded to include more input parameters, and a rational and logical method is developed for determining likelihood functions from existing information.

## Table of Contents

List of Tables .....	xx
List of Figures .....	xxiii
CHAPTER 1: INTRODUCTION .....	1
1.1 Background on Enhanced Oil Recovery .....	1
1.2 The Motivation for the Research .....	2
1.3 Objectives of this Study .....	3
1.3.1 Sub-Objective One: Establish a Predictive Model.....	3
1.3.2 Sub-Objective Two: Evaluate the Predictive Model .....	3
1.3.3 Sub-Objective Three: Establish a Decision Analysis Process and Demonstrate the Process through an Example.....	4
1.4 Layout of Thesis .....	4
CHAPTER 2: BACKGROUND ON ENHANCED OIL RECOVERY METHODS, MODELLING, AND DECISION ANALYSES.....	6
2.1 Introduction.....	6
2.2 General Background on Conventional Recovery .....	7
2.3 Discussion of the Isothermal Enhanced Oil Recovery Methods .....	9
2.3.1 Polymer Flooding.....	11
2.3.2 Surfactant-Polymer Flooding.....	12
2.3.3 Alkali-Surfactant-Polymer Flooding .....	14
2.3.4 CO <sub>2</sub> Flooding .....	16
2.4 Enhanced Oil Recovery Models .....	17
2.4.1 Koval's Method .....	17

2.4.2 Chemical Flood Predictive Model .....	18
2.4.3 UTCHEM.....	19
2.4.4 Enhanced Oil Recovery Rate Model.....	21
2.5 Decision Analyses.....	23
2.5.1 Sanz and Miller's Paper .....	23
2.5.2 Barua et al. Paper .....	24
2.6 Summary .....	25
<b>CHAPTER 3: DEVELOPMENT OF THE SIMPLIFIED ENHANCED OIL RECOVERY METHOD .....</b>	<b>26</b>
3.1 Introduction.....	26
3.2 Idealized One Dimensional Flow Model .....	26
3.2.1 Description of the Simplest Case.....	26
3.2.2 Description of the Simple Case for an EOR Flood.....	29
3.3 The Actual Condition with Two Banks .....	32
3.4 The Actual Condition with Three Banks .....	33
3.5 Predicting Frontal Velocities .....	34
3.5.1 Application of the Conservation of Mass .....	35
3.5.2 Application of the Frontal Advance Formula .....	37
3.5.3 Application of the Fractional Flow Curve for the Surfactant-Polymer and Alkali-Surfactant-Polymer Cases.....	38
3.5.4 Application of the Fractional Flow Curve for the CO <sub>2</sub> Flood Case.....	50
3.6 Koval's Method .....	54
3.6.1 Koval's Assumptions .....	54

3.6.2 Development of Koval's Equations .....	54
3.7 Development of the Simplified Enhanced Oil Recovery Model .....	58
3.7.1 Derivation of the Fractional Flow Equation for the Simplified Enhanced Oil Recovery Method .....	58
3.7.2 Derivation of the Oil Cut Equation .....	60
3.7.3 Summary of Critical Equations for the Simplified Enhanced Oil Recovery Method .....	61
3.7.4 Discussion of the Input Parameters for the Simplified Enhanced Oil Recovery Method .....	63
3.7.5 Discussion of Other Important Parameters for the Simplified Enhanced Oil Recovery Method .....	66
3.8 Summary of the Simplified Enhanced Oil Recovery Method .....	67
CHAPTER 4: EVALUATION OF THE SIMPLIFIED ENHANCED OIL RECOVERY METHOD .....	68
4.1 Introduction .....	68
4.2 General Discussion of the Data Used for Validation .....	69
4.3 The Evaluation Process .....	69
4.3.1 Necessary Field Data .....	69
4.3.2 The Fitting Process for Surfactant-Polymer and Alkali- Surfactant-Polymer Floods .....	72
4.3.3 Fitting the Fractional Flow Curve .....	76
4.3.4 The Fitting Process for CO <sub>2</sub> Floods .....	79
4.4 Summary of the Fits for All of the Flood Types .....	80
4.5 Analysis of the Fits .....	84
4.5.1 Comparison of Scale for SP Floods .....	85

4.5.2 Comparison of Flood Types; SP and CO <sub>2</sub> .....	89
4.5.3 Discussion of the Outliers and Fitting Issues .....	92
4.6 Comparison of Fittings for Similar Projects .....	94
4.6.1 Comparison of Pilot and Field Scale Projects.....	94
4.6.2 Comparison of Same Scale Projects .....	97
4.7 Conclusions .....	98
Chapter 5: Development of an Economic Model .....	100
5.1 Introduction.....	100
5.1.1.1 Economic Criteria .....	100
5.2 Economic Parameters.....	101
5.2.1 Generic Factors .....	101
5.2.1.1 Oil Price .....	102
5.2.1.2 Taxes and Royalties .....	103
5.2.1.3 Injection, Treatment, and Disposal Costs .....	104
5.2.1.4 Start Up and Maintenance Costs.....	104
5.2.1.5 Inflation.....	105
5.2.2 Factors Unique to Specific Floods .....	105
5.2.2.1 Polymer Expenses.....	106
5.2.2.2 Surfactant-Polymer Expenses .....	106

5.2.2.3 Alkaline-Surfactant-Polymer Expenses .....	106
5.2.2.4 CO <sub>2</sub> Expenses.....	107
5.2.3 Summary of Input Parameters .....	107
5.3 Economic Model.....	108
5.3.1 Income.....	108
5.3.2 Expenses .....	109
5.3.3 Net Profit.....	111
5.3.4 Cumulative Discounted Cash Flow .....	111
5.4 Discussion of the Economical Cap .....	112
5.5 Example of the Economic Model .....	113
CHAPTER 6: SENSITIVITY ANALYSIS .....	115
6.1 Introduction.....	115
6.2 Sensitivity Analysis Process .....	115
6.3 Base Cases .....	117
6.3.1 Review of the input variables .....	118
6.3.2 Base Case Plots .....	122
6.4 Sensitivity Analysis of Surfactant-Polymer Floods.....	125
6.4.1 Setup for Surfactant-Polymer Floods.....	125
6.4.2 Results for the Surfactant-Polymer Flood Analysis.....	127
6.4.2.1 Change in Oil Saturation.....	127

6.4.2.2 Total Pore Volume .....	131
6.4.2.3 Price of Oil .....	133
6.4.2.4 Well Spacing .....	134
6.4.2.5 Surfactant Expenses .....	136
6.4.2.6 Heterogeneity Factors .....	138
6.4.2.7 Least Sensitive Parameters for the Simplified Enhanced Oil Recovery Method.....	142
6.4.2.8 Upfront and Maintenance Expenses .....	146
6.4.2.9 Ad-Valorem Tax .....	148
6.5 Sensitivity Analysis of Alkali-Surfactant-Polymer Floods.....	149
6.5.1 Setup of Analysis of Alkali-Surfactant-Polymer Flood Analysis..	149
6.5.2 Results for the Surfactant-Polymer Flood Analysis.....	149
6.6 Sensitivity Analysis of CO <sub>2</sub> Floods .....	152
6.6.1 Setup of CO <sub>2</sub> Flood Analysis .....	152
6.6.2 Results of CO <sub>2</sub> Flood Analysis .....	153
6.7 Summary of the Sensitivity Analysis.....	155
CHAPTER 7: SET UP OF DECISION ANALYSIS FRAMEWORK FOR ENHANCED OIL RECOVERY .....	158
7.1 Introduction.....	158
7.2 Background on Decision Making Process .....	158
7.2.1 Decision Trees .....	160
7.3 General Discussion of the Enhanced Oil Recovery Decision.....	161
7.3.1 The Model for the Water Flood Alternative .....	162

7.4 Construction of the Decision Tree Structure for the Analysis .....	165
7.4.1 Construction of the Prior Decision Tree .....	165
7.4.2 Construction of the Posterior and Preposterior Decision Trees.....	166
7.4.2.1 Posterior Decision Tree.....	166
7.4.2.2 Preposterior Decision.....	167
7.5 Non-Informative Prior Probabilities .....	168
7.5.1 Principle of Insufficient Reason Applied to Input .....	169
7.5.1.1 Rationality.....	169
7.5.1.2 Consistency .....	171
7.5.2 The Decision-Based Method.....	175
7.5.2.1 Theory of the Decision-Based Method .....	175
7.5.2.2 Example of DBM Dealing with Rationality and Consistency .....	182
7.5.3 Applying Monte Carlo Simulation to the Decision Based Method .....	186
7.6 Bayes' Theorem.....	188
7.6.1 Bayes' Theorem Definition.....	188
7.6.2 Bayes' Theorem Example.....	190
7.7 Summary .....	191
CHAPTER 8: EXAMPLE OF THE DECISION ANALYSIS .....	193
8.1 Introduction.....	193
8.2 Performing the Decision Analysis for the Thesis Decision .....	193
8.3 Outline for Example A.....	194

8.3.1 Step 1: Setup the Decision Tree.....	194
8.3.2 Step 2: Establish the Conditions for the Enhanced Oil Recovery Decision .....	194
8.3.3 Step 3: Establish the Non-Informative Prior Probability Distributions for the Analyzed Parameters.....	196
8.3.3.1 Applying the Decision-Based Method to the Study's Decision .....	197
8.3.3.2 Sensitivity Analysis of the Decision Based Method.....	197
8.3.3.3 Sensitivity of Parameter Intervals.....	198
8.3.3.4 Sensitivity of Parameter Combinations .....	200
8.3.3.5 Sensitivity of Parameter Ranges .....	206
8.3.3.6 Applying Monte Carlo Simulation to the Decision Based Method with Multiple Parameters .....	208
8.3.3.7 Summary of Sensitivity Analysis for the Decision Based Method .....	210
8.3.3.8 Applying the Decision Based Method for Example A ...	211
8.3.4 Step 4: Determine the Expected Utilities of the Alternatives for the Non-Informative Prior Decision .....	212
8.3.5 Step 5: Set Up the Posterior Decision.....	213
8.3.6 Step 6: Determine the Expected Utilities of the Alternatives from the Posterior Analysis .....	215
8.3.7 Step 7: Set Up of the Preposterior Decision .....	218
8.3.8 Step 8: Determine the Value of Information.....	219
8.4 Updating the Non-Informative Prior, Example B.....	220
8.5 Applying Monte Carlo Simulation to the Decision Analysis .....	222
8.5.1 Monte Carlo Simulation Example .....	225

8.6 Summary .....	227
CHAPTER 9: CONCLUSIONS AND FUTURE WORK.....	229
9.1 Review of the Research .....	229
9.2 Conclusions.....	229
9.2.1 Conclusions about the Simplified Enhanced Oil Recovery Method .....	230
9.2.2 Conclusions about the Decision Making Process .....	231
9.3 Recommendations for Future Work.....	232
APPENDICES .....	234
Appendix A: Evaluation Fits .....	234
Appendix B: Relationships Between Reservoir Characteristics and Fitting Parameters.....	300
Appendix C: Sensitivity Analysis Plots.....	314
Appendix D: Extra Plots for the Demonstration of the Decision Based Method	378
Appendix E: Nomenclature.....	394
References.....	400

# **CHAPTER 1: INTRODUCTION**

## **1.1 Background on Enhanced Oil Recovery**

As oil prices and global for oil continue to steadily rise, oil producers have two options; start new fields or attempt recovering oil left behind in existing reservoirs (Belhaj and Lay 2008). Accessibility and start-up costs associated with producing oil from new fields make only large and rare fields economically viable options, and therefore enhanced oil recovery (EOR) is receiving more attention.

Most fields depend on primary and secondary isothermal recovery methods for oil production, which leaves approximately 40 to 60% of the oil in a reservoir unrecovered. EOR methods such as surfactant-polymer (SP), alkali-surfactant-polymer (ASP), and CO<sub>2</sub> flooding all have the ability to recover a fraction of the oil remaining in the reservoirs. Such methods can economically recover upwards of 15% of the original oil in place (Lake 1989).

Each method has its advantages and disadvantages. SP and ASP floods improve oil recovery through the mobilization of residual oil and improved sweep through the reservoir (Austad and Milter 2000). SP flooding is more expensive than ASP flooding, but arguably more dependable because of more field experience. CO<sub>2</sub> flooding mobilizes residual oil at a considerably lower cost than the other methods, but it usually reduces the sweep of the reservoir (Walsh and Lake 2008). Therefore, careful consideration of the advantages and disadvantages is required during the selection process between the three methods to ensure that the economically most attractive option is selected.

## **1.2 The Motivation for the Research**

The technologies associated with EOR have existed for over half a century, with early pilot tests performed in the 1960's. However, the financial risks associated with the projects have prevented widespread use (Hartshorne and Nikonchik 1984; Stover 1988; and Bae 1995). Furthermore, the lack of history and experience with the technologies has created uncertainty with designing and predicting the performance of EOR projects. Therefore, as companies look towards EOR, they must balance the technological risk with economic potential.

Several researchers and engineers have attempted to minimize the risk associated with EOR by creating complex models that attempt to accurately predict the performance of projects (Paul et al. 1982, Saad et al. 1989, and Walsh and Lake 2008). Such models are limited by the uncertainty associated with the large number of required inputs.

Another popular method for analyzing and minimizing risk is to perform a decision making analysis that allows for a fair and unbiased selection process between the different methods. Such analyses typically take into account all possible outcomes; therefore, they require simple models that allow for many simulations to capture all of the outcomes. Several researchers have used simple models in decision analyses, but failed to create close representations of the oil recovery history (Barua et al., and 1986, Sanz and Miller 1994). Furthermore, the approaches used by many to set up the decision analyses typically create unintentional bias that alters the decision (Min 2008). Therefore, there is a need for a simplified but physically meaningful model of EOR

performance and a need to use this model to evaluate EOR in a formal decision framework.

### **1.3 Objectives of this Study**

The main objective of this study is to provide decision support for EOR projects. The support comes in the form of decision analysis framework laid out for a value of information analysis of a pilot for EOR. To meet the objective several steps and sub-objectives have to be completed.

#### **1.3.1 One: Establish a Predictive Model**

A model for predicting the oil production history of an EOR project such as SP, ASP, and CO<sub>2</sub> floods is necessary. It must be simple with as few physically meaningful variables as possible for predicting technical performance. The predictions must be able to capture the general shape of the oil production history curve so that accurate economical predictions are possible. Along with the predictive model there must be an economic model that properly accounts for all expenses and revenue associated with an EOR project so that an accurate economic value of the project can be created.

#### **1.3.2 Two: Evaluate the Predictive Model**

The predictive model must be evaluated against actual pilot and field scale projects to assess the model's ability to forecast accurate oil production history. This evaluation also provides and typical values data and ranges associated with the input variables for the model that match real data.

### **1.3.3 Three: Establish a Decision Analysis Process and Demonstrate the Process through an Example**

A decision analysis framework is needed to support the decision analysis. To establish an unbiased and consistent starting point, for assessing probabilities in this framework, a decision-based method is evaluated and used. A realistic example using this framework provides generic insight about the value of information of a pilot test.

## **1.4 Organization of Thesis**

The thesis is organized in an order similar to the layout of the sub-objectives. Chapter 2 is generic overview of EOR processes and a review of similar decision analysis work. Chapter 3 explains the development of the predictive model and the meaning of the parameters associated with it. The evaluation of the predictive model and ranges for the parameters associated with the parameters of the model are discussed in Chapter 4. Chapter 5 explains the economic model and how revenue and expenses are accounted. Chapter 6 is a sensitivity analysis of all of the parameters associated with the predictive model and the economic model. This chapter provides some insight into how all the parameters influence value of an EOR project. The set up of the decision analysis is discussed in Chapter 7. The method for performing a value of information analysis of a pilot test for an EOR project is discussed and illustrated in Chapter 8. Conclusions about the predictive model and the decision analysis process are reviewed in Chapter 9. In the appendices are a collection of the all fields used in the evaluation of the predictive model (Appendix A), a collection of plots showing correlations between predictive model's parameters and field properties (Appendix B), collection of the plots created for the

sensitivity analyses (Appendix C), plots demonstrating the decision based method (Appendix D), and a summary of the nomenclature used throughout the thesis (Appendix E).

## CHAPTER 2: BACKGROUND ON ENHANCED OIL RECOVERY

### METHODS, MODELLING, AND DECISION ANALYSES

#### 2.1 Introduction

Countries all around the world are currently industrializing and therefore require large amounts of energy, especially petroleum. Figure 2-1 shows how the per capita demand of several countries has grown over the past century. Developed countries, such as the US and Japan, have leveled off in terms of per capita demand; however, over the past couple of decades, the heavily populated countries of China and India have begun to industrialize and their development will cause a significant increase in demand.

**Figure 2-1 Plot of Oil Consumption during Industrialization of US, Japan, South Korea, China, and India (Jackson 2007)**

The new demand will strain current resources of oil and force oil companies to look towards either new fields or become more efficient with existing ones. Starting a new field is an economic endeavor that is not attractive unless it is a huge field.

Therefore, companies are considering a wide variety of techniques to recover oil that is often unrecovered under conventional methods. These techniques fall under the category of enhanced oil recovery (EOR) methods (Lake 2008).

## **2.2 General Background on Conventional Recovery**

The life of a typical reservoir goes through several stages of recovery. The first stage, known as primary recovery, uses the natural pressure gradient that exists within a reservoir to drive oil production. Once the pressure in the reservoir decreases to a point where recovery is no longer economical, secondary recovery is initiated. In general, about 12 to 15 percent of a reservoir's original oil in place (OOIP) is recovered during primary (Walsh and Lake 2003).

Secondary recovery is where either external energy is supplied into the reservoir through means, such as pumps, or a pressure gradient is regenerated through the injection of a fluid, such as water. A common form of secondary recovery is water flooding, a process where water is injected into the reservoir that displaces a fraction of the remaining oil. About another 15 to 20 percent of the OOIP is economically recovered by secondary flooding (Walsh and Lake 2003).

Once water flooding is no longer economical, oil companies must decide whether to attempt tertiary recovery or to abandon the reservoir. There may be as much as 65 to 70 percent of the OOIP may not be recovered. Figure 2-2 is a comparison of the ultimate oil recovery efficiencies with conventional methods for projects from around the world.

**Figure 2-2 Comparison of the Distribution of Ultimate Oil Recovery Efficiencies with Conventional Methods for Projects from around the World (Lake 2008)**

There are a variety of options for tertiary recovery including chemical injection, steam injection, in-situ combustion, and solvent injection. Tertiary recovery is often referred to as EOR. EOR methods improve recovery by mobilizing oil not typically mobilized by conventional recovery. The newly mobilized oil leads to an increase in rate of oil production and the final volume of produced oil. These methods have the potential to recover some of the remaining OOIP; however, economical limitation allow for them to only recover about five to 15 percent of the OOIP. The technology has existed for decades with particular interest during the 1980s when oil prices spiked (Lake 2008).

This thesis focuses on a specific group of isothermal EOR methods including surfactant-polymer (SP), alkali-surfactant-polymer (ASP), and carbon dioxide (CO<sub>2</sub>)

injection. SP and ASP floods are often referred to as chemical EOR methods and CO<sub>2</sub> flooding is a form of a gas EOR method.

### 2.3 Discussion of the Isothermal Enhanced Oil Recovery Methods

Oil is not recovered during a water flood because it is either trapped by capillary forces or the water completely bypasses the oil. The capillary forces are due to surface tension, and they compete with the flow velocity, and viscosity of the injected water. The forces trap oil in small pores that make it very difficult to recover with water because extremely high pressure gradients are required. This trapped oil is often referred to as residual oil. The effect of the capillary force is characterized by the capillary number,  $N_C$ , which is defined as

$$N_C = \frac{\mu_w v}{\sigma} \propto \frac{\text{Driving Force}}{\text{Resisting Force}}$$

**Equation 2-1**

where  $\sigma$  is the oil-water interfacial tension,  $\mu_w$  is the viscosity of the displacing fluid, and  $v$  is the effective flow rate. Figure 2-3 is a plot of residual oil saturation ( $S_{or}$ ) against  $N_C$  for a typical reservoir. To mobilize residual oil, either the surface tension of the water must be reduced, or the water's viscosity must greatly increase (Austad and Milter 2000).

**Figure 2-3 Residual Oil Saturation against Capillary Number for a Typical Reservoir (Austad and Milter 2000)**

The oil that is bypassed is missed because of poor sweep between the injectors and producers. The injected water tends to miss the oil because of either an unfavorable mobility between the oil and water or because of the heterogeneity of the reservoir. Mobility is the ratio of the permeability of a porous material to a given phase divided by the viscosity of that phase. Poor areal sweep is often a result of instability between the water and oil, which creates fingering of the low viscosity water into the oil. Poor vertical sweep is typically caused by heterogeneity of the layers of the reservoir (Sorbie 1991). As a result of the poor sweep, a very large volume of water must be injected so that water can come into contact with all of the oil that is not trapped by capillary pressures.

Each isothermal EOR method addresses the aforementioned issues to some degree; however, each method has its own benefits and restrictions that must be considered prior to project initiation.

### 2.3.1 Polymer Flooding

A very common form of EOR is polymer flooding. Polymer floods are floods where polymer is mixed with water to create a viscous fluid that is injected into the reservoir. The more viscous fluid reduces the mobility ratio between the oil and water, which improves the sweep of the injected fluid for the reservoir. The mobility ratio,  $M$ , is the ratio of the mobilities of oil and the displacing fluid, as shown

$$M = \frac{(k/\mu)_w}{(k/\mu)_o}$$

**Equation 2-2**

where  $k$  is permeability,  $\mu$  is viscosity, and the subscripts  $w$  and  $o$  stand for the displacing fluid and oil, respectively (Sorbie, 1991). The displacing fluid is water mixed with admixtures or solvents.

As a result of the better sweep, a spike in oil cut is generated and the remaining non-residual oil is recovered more rapidly, which reduces the life of the field (Sorbie 1991). The higher rate of recovery leads to a higher economical value for the produced oil than would exist if water flooding were continued, because early returns are more valuable when considering the time value of money.

Polymer floods also mobilize a small fraction of the residual oil because of the increase in viscosity; however, this effect is often neglected. The viscosity of the water usually needs to be increased by several orders of magnitude in order to mobilize a significant volume of residual oil (Sorbie 1991, Austad and Milner 2000).

Polymer floods are best suited for fields where the mobility ratio between water and oil causes fingering and heterogeneity causes channeling. Floods with mobility ratios greater than five typically experience these effects (Sorbie 1991). Other factors that to be considered include temperature, permeability, porosity, pH, clay content, fluid injectivity, salinity, and hardness of both the injected and in-situ fluids. These factors influence the degradation and adsorption of the polymer which in turn affect the effectiveness of the flood (Sorbie 1991). Injectivity of a fluid is the rate and pressure at which the fluid can be pumped into the reservoir without creating fractures in the formation. Injectivity could be of considerable importance because it may limit the injection rate for a significant portion of the flood's life which in turn leads to a lower production rate and lower overall profits when considering the time value of money.

Despite the wide range of factors, there is considerable comfort with designing polymer floods because they are relatively inexpensive, extensive flood preparations are not usually necessary and a wide variety of case histories and research exists. The most critical economic aspect is to build a mixing plant and the cost of the polymer. Other types of EOR floods include polymers because of the low cost and the added benefits with sweep (Sorbie 1991).

### **2.3.2 Surfactant-Polymer Flooding**

Surfactant-polymer (SP) floods are designed to both improve the sweep of the reservoir as well as mobilize residual oil. SP floods are often referred to as micellar-polymer flooding or microemulsion flooding. A surfactant is a substance that lowers the surface tension between the two immiscible phases of oil and water. By reducing the

surface tension, the capillary forces are reduced and more oil is mobilized. Common forms of surfactants are detergents and soaps (Lake 1989).

There are several phases to an SP flood that involve the injection of distinctly different slugs. Historically, the first phase involves the injection of preflush slug designed to establish more favorable reservoir conditions for the surfactant slug by adjusting the salinity of the fluids in the reservoir. The second phase is injecting a slug of surfactant mixed with injection brine. The slug size is typically small (less than 0.25 total pore volumes of the reservoir) and the concentration of surfactant ranges between two and eight percent of the weight of injected fluids. The surfactant slug is followed by a slug of polymer and then followed by chase water. Some studies suggest that polymer could be mixed with surfactant as well as a polymer slug and the preflush may not be necessary (Lake 1989).

The ideal scenario for a SP flood is for reservoirs where the  $S_{or}$  is high, heterogeneity and mobility is an issue, the in-situ conditions are favorable for the surfactant and polymer, and the price of oil is high. Designing for a SP flood is challenging because the chemicals are sensitive to wide variety of factors including rock type, salinity, pH, heterogeneity of the reservoir, injectivity, hardness of fluids, clay content, viscosities, temperature, and pressure. Co-solvents such as alcohol may be needed to prevent gel formation and other complications (Austad and Milner 2000). Furthermore, there are few case histories of full-scale implementations and therefore little experience to draw from for assistance. The few case studies that do exist are mostly

from the 1970s and 1980s when SP flooding was popular and considered to be a viable option (Lake 2008).

There are several lab studies and research projects regarding SP flooding. The overall conclusion is that SP floods can provide a significant technical success as a large volume of the  $S_{or}$  can be recovered from core floods. However, at the field-scale there tend to be issues when trying to ensure good contact between oil and injected chemicals. Therefore, the field scale projects are not as technically successful as flooded lab cores. There also appears to be a shift in recommended flood design. Early projects injected very small slugs with high surfactant concentration. More recent projects seem to lean towards larger slug sizes with lower concentrations of surfactant.

The costs associated with a surfactant flood are high because the surfactant is expensive and most fields will need some development. The development includes new injection and production wells because smaller well spacings are needed in order to improve chemical and oil contact (White et al. 1986).

Since the 1980s, the overall consensus of the oil companies is that this method is a technical risk and uneconomical unless the price of oil is very high (Austad and Milner 2000). With the current oil prices hovering around \$80/STB (Bloomberg 2010), SP flooding has once again become economically viable. The issue that remains to be overcome is the technical uncertainty involved with such a project.

### **2.3.3 Alkali-Surfactant-Polymer Flooding**

Alkali-surfactant-polymer (ASP) floods are very similar to SP floods. Both EOR methods improve oil recovery by mobilizing residual oil and improving volumetric

sweep of the reservoir. The most significant difference between the two is that in ASP floods, alkaline chemicals are used along with surfactants and polymers. The alkali helps to reduce the adsorption of the surfactant and produces additional surfactant when reacting with in-situ oil. The alkali therefore produces a surfactant in the reservoir that works with the synthetic surfactant to mobilize residual oil (Hirasaki et al. 2008).

Overall, ASP floods have similar sensitivity to the same factors as SP floods. ASP floods are more sensitive to the rock type of the reservoir and have the added challenge of dealing with alkali consumption because of the alkali reacting with the oil. Furthermore, ASP floods are more likely to need a preflush to condition the reservoir, which delays profitable recovery for the project (Hirasaki et al. 2008).

Just as with SP floods, ASP floods have similar stages of injection. They start with a preflush, followed by an ASP slug, followed by a polymer slug, and then the chase water. The hardness of the injected fluid needs to be carefully monitored and maintained during the injection of the alkali (Wyatt et al. 2008).

Similar economic costs are associated with ASP floods as SP, including building new wells, mixing plants, and chemical costs. Overall, the cost of the chemicals are significantly lower as only a fraction of surfactant is needed and alkaline chemicals are not very expensive (Wyatt et al. 2008).

As long as the in-situ properties allow an ASP flood to work and the  $S_{or}$  is high, then an ASP flood can be a strong option because it is not a very expensive method, especially when compared to SP floods. However, ASP flooding is a relatively young technology and there are very few case studies at the field level.

### 2.3.4 CO<sub>2</sub> Flooding

CO<sub>2</sub> flooding is a type of solvent flooding method. It can be either be a miscible or immiscible process (Walsh and Lake 2008).

The main mechanism of oil recovery for CO<sub>2</sub> flooding is its ability to reduce surface tension between oil and water. Under lab conditions, it can recover nearly all of the residual oil in a core. At the field-scale a project typically produces less sweep of the reservoir than predicted. The viscosity of the CO<sub>2</sub> solvent is a very low compared to the oil, creating a poor mobility ratio between the solvent and the oil. To improve mobility, CO<sub>2</sub> is injected with water to increase the viscosity of the solvent. This process is known as a water alternating gas (WAG) process. CO<sub>2</sub> floods are designed with a WAG ratio in mind. The WAG ratio is the ratio of water to CO<sub>2</sub> solvent for the injected fluid. Lower WAG ratios have a higher CO<sub>2</sub> concentration and tend to lead to better residual oil mobilization, but poorer sweep. A balanced design is required for an economically optimal recovery (Walsh and Lake 2008).

The most critical criteria for a CO<sub>2</sub> candidate reservoir are low oil viscosity and high  $S_{or}$ . Rock type, pressure, and injectivity are other factors to be considered (Lake 2008).

The costs associated with CO<sub>2</sub> flooding are usually lower than for SP and ASP because less initial preparation work is required and the cost of the solvent is relatively inexpensive. The initial costs are low because larger well spacings, such as those used with water flooding, can be adequately used with CO<sub>2</sub> flooding (Mohan et al. 2008).

## **2.4 Enhanced Oil Recovery Models**

Several models and methods exist to assist with designing and predicting the performance of an EOR process. Each method has its advantages and disadvantages. Some look to accurately and precisely forecast the production history of a field, while others attempt to predict only basic features with a simple model.

### **2.4.1 Koval's Method**

Koval (1963) discusses a simple method to predict the behavior of a secondary recovery process through the use of a variable known as a Koval factor. The Koval factor is used to account for the effect of heterogeneity on a flood's behavior. Some have attempted to apply the model directly to EOR floods as well as secondary recovery.

The main advantage to the method is its simplicity. The method is a set of equations based on a single non-dimensional factor, the Koval factor. The simplicity of the method limits it from being able to capture all aspects of a flood. For example Koval's method predicts an instantaneous jump in oil cut that remains constant until breakthrough of the injected fluids. This behavior is not the case for a tertiary flood in the field or even the lab, because there is typically a delay between start of injection and the peak oil cut at the producers. Furthermore, there is typically an increase in oil cut rather than an instantaneous jump. Missing these characteristics can impact the economics of the project. The method is however able to capture the overall behavior of a declining oil cut and to some degree characterize the life of the flood in non-dimensional terms.

### 2.4.2 Chemical Flood Predictive Model

A simple model known as the chemical flood predictive model (CFPM) was developed for SP floods by Paul et al. (1982). The model is designed to use correlations to relate factors that influence oil recovery. Particular attention is paid to the capillary number, heterogeneity (Dykstra-Parsons coefficient), wettability, and surfactant sorption. From the correlations and fractional flow theory, oil breakthrough, peak oil rate, and project life are estimated.

CFPM produces a triangular pattern of oil production history, as shown in Figure 2-4. The left vertex reflects zero oil production and occurs when oil breakthrough is expected to occur. The apex is at the level and time when the peak oil production is expected. The right vertex is at an oil production of zero at the time when the flood is expected to end. The area under the curve estimates the total volume of recoverable oil.

Figure 2-4 is an example of a prediction from CFPM compared with field data.

Figure 2-4 Example of CFPM against Data from a Field Surfactant-Polymer Flood (Paul et al. 1982)

CFPM is a simple model that does a better job than Koval's method in dealing with delay and increasing oil cut. The triangular curve does capture several important aspects of the flood behavior. Even though it does not create a close representative shape of the flood behavior, the triangular curve probably allows for a decent rough approximation of the monetary value of the project. Furthermore, because it is based on real tangible values, it can provide reasonable starting points when going through multiple simulations.

The main limitation of CFPM is that it creates a rough approximation of the production history curve. Another issue with the model is that it is strictly limited to sandstone reservoirs and SP floods.

#### **2.4.3 UTCHEM**

UTCHEM was developed at The University of Texas at Austin. It is designed to create accurate three dimensional reservoir simulations for chemical flooding. The simulator takes into account three-phases and up to 19-component flow. It is based on material mass-balance equations and accounts for several major physical phenomena. UTCHEM can handle any of the factors that are thought to influence the effectiveness of a chemical flood. It has been evaluated against several sets of lab, pilot, and field data (Saad et al. 1989).

UTCHEM is the "gold standard" simulator when compared to the other models discussed. Simulations generated by UTCHEM require dozens of input variables and multiple simulations are time-consuming. Table 2-1 is an example of the required inputs for UTCHEM. Most of the inputs are immeasurable and therefore contain considerable

uncertainty. Figure 2-5 is an example of the fit possible with the simulator. The simplified enhanced oil recovery model (SEORM) was also fitted against the production history in Figure 2-5.

**Table 2-1 Example of the Required Simulation Parameters for UTCHEM, from the Big Muddy Pilot (Saad et al. 1989)**

Parameter	Value	Parameter	Value	Parameter	Value
$C_{2PLC}^*$	0.0	$S_{1W}$	0.32	$A_{P2}$	2,700.0

Figure 2-5 Example of UTCHEM Fit against Data from the Big Muddy Pilot (Saad et al. 1989)

#### 2.4.4 Enhanced Oil Recovery Rate Model

The EOR rate model was developed by Walsh and Lake (2008) for the purpose of predicting a tertiary miscible flood. The approach is based on a hyperbolic decline curve and material balance. The model breaks down an EOR flood into three parts. The first part is the delay between when the flood is initiated and first response occurs at the producer. During this part, it is assumed that the decline curve modeling the water flood is continued. The second part is a linear increase in oil production till an assumed peak oil rate is reached. The third part is a decline in production till the production becomes zero. The model involves up to nine input parameters. The values used for the parameters are based on empirical correlations or ranges based on previous fits. Figure

2-6 is an example of the EOR rate model being applied. The example is from the Wertz field and is of a CO<sub>2</sub> flood. The model can be altered to fit most data sets well.

**Figure 2-6 Example of EOR Rate Model Fit against Data from the Wertz Field (Walsh and Lake 2008)**

The advantage of the model is that it provides a closer match than the other simple models with relatively few inputs. This model does allow one to perform multiple simulations quickly and could provide a more precise prediction of the monetary value of a project. However, there are nine parameters that are essentially unknown and not easily predicted prior to a flood because they are empirical. Distributions and correlations do exist to help predict these values, but they are based on very few data sets, all of which are CO<sub>2</sub> floods. Therefore, considerable evaluation would be required to ensure the model can work with other types of floods and to determine more accurate ranges and correlations.

## **2.5 Decision Analyses**

Most simulators and models are not very accurate at prediction, even if they involve a significant amount of detail. A decision analysis that takes into account all of the possible outcomes for an EOR flood is no longer handicapped by a model's inaccuracy. By taking in account extremes, one can interpret the entire spectrum of possible outcomes.

Several papers have been published that attempt to demonstrate how one can use a simple model as part of decision analysis that either tries to determine the optimal design or decision for an EOR project. Two papers in particular are Sanz and Miller's (1994) and Barua et al. (1986).

### **2.5.1 Sanz and Miller's Paper**

Sanz and Miller created a decision analysis method designed to assist with determining the probability that a design input is optimal for an SP flood. The authors used a model known as MCPALK. The utilities for any outcome were based on the monetary value of the project, as determined by the discounted cash flow. The input parameters for the model were divided into decision variables and stochastic variables. All stochastic variables were assumed to have continuous distributions, while finite distributions were used for the design variables. Sensitivity analyses were performed as a means to rank and identify the most influential stochastic parameters.

The authors created a method that studies and determines the optimal value for a design variable individually, based on the outcomes of the stochastic variables. Monte

Carlo simulation was implemented to represent the possible combinations of values to occur.

Their method applies for scenarios where the engineer has already determined the scale of the SP flood. The analysis does not explicitly take into account information from a pilot nor does it properly explain how the probability distributions for the stochastic variables are determined. The authors suggest that a user inputs probabilities for the variables based on their judgment.

### **2.5.2 Barua et al. Paper**

The purpose of the paper was to develop a method that allows one to make technical and business decisions about SP flooding when there is considerable uncertainty. Their method allows an engineer to quickly evaluate the economic potential of a field for an EOR flood and to compare EOR methods against other alternatives. The authors used CFPM as the SP flood modeling tool and discounted cash flow for creating the utilities. A Monte Carlo simulator was used to reflect the uncertainty.

The authors performed a similar analysis as Sanz and Miller, except fewer parameters were studied. Barua's work has the advantage that it can handle comparing different project alternatives as well as determining how a particular parameter influences the decision. Barua's has the same issue with the input probabilities and lack of pilot information as Sanz and Miller.

## **2.6 Summary**

Enhanced oil recovery methods inherently have significant risk because of the uncertainty of the characteristics of a reservoir and the economic future. They are also very expensive and time consuming endeavors that must be carefully evaluated prior to a project's commencement. Several researchers have created models designed for both preliminary analysis as well as more detailed forecasting of the technical performance of an EOR flood. These models allow an engineer to study the potential outcomes as well as determine where the majority of uncertainty lies for a project. Decision analyses allow the engineer to then determine what the expected value of a project based on certain parameters. Researchers have used decision analyses and simple models to evaluate a field's potential for EOR and to determine starting points for creating optimal designs for the EOR flood.

Based on the review of existing literature on EOR and relevant modeling and decision analyses, a new simple model that better handles the shape of a typical EOR oil production curve is needed. Also needed is a method that defensibly establishes probabilities for the input parameters and a decision analysis that accounts for the value of pilot information.

## **CHAPTER 3: DEVELOPMENT OF THE SIMPLIFIED ENHANCED OIL RECOVERY METHOD**

### **3.1 Introduction**

A model is necessary to predict how a field will behave through the course of its life so that possible production and economic performance can be represented. Currently, several models exist to model a reservoir during a chemical flood; however, they require many input variables that require an in depth understanding of the input parameters and how the programs work. Furthermore, such programs can be cumbersome when one tries to run through multiple scenarios. The objective of this chapter is to explain the development and theory behind the simplified enhanced oil recovery method, which is designed for quick simulations of accurate oil production history curves.

The simplified enhanced oil recovery method (SEORM) models oil recovery in one dimension and it is based on fractional flow theories. The method also has Koval's model at its foundation.

### **3.2 Idealized One Dimensional Flow Model**

#### **3.2.1 Description of the Simplest Case**

As a starting point for envisioning the problem, a basic one dimensional flow model between the injector and producer is considered. The following assumptions are made:

- 1) mass is conserved
- 2) the system is linear
- 3) the fluids are ideal and incompressible
- 4) one dimensional flow through a homogenous, isotropic, and isothermal material
- 5) the initial distribution of the fluids are uniform
- 6) no more than two phases flowing at once
- 7) no more than three flowing banks
- 8) Darcy's law applies
- 9) there is continuous flow
- 10) there is continuous and constant injection of displacing fluid
- 11) the banks are locally segregated
- 12) gravity and capillary effects are negligible
- 13) dispersion can be ignored
- 14) the top and bottom boundary of the reservoir are no-flow boundaries

If these assumptions are applied to a two bank flood, much like in a water flood, the reservoir will experience a piston like displacement between the injector and producer, as shown in Figure 3-1. The flood will consist of two banks, one for the initial condition and another for the injected fluid. Point A marks the front of the injected bank.

A bank is a portion of the fluids within a reservoir that has similar composition of its components in terms of fractional flow and saturation. A component is a distinct molecular entity, such as water or oil. For example, the initial bank is characterized by the saturations of the components that initially existed prior to flooding.

**Figure 3-1 Profile of a Snap Shot in Time of a One Dimensional Flow for a Piston Like Two Bank Flow**

The two banks in Figure 3-1 consist of the same components, oil and water, but at different saturations. The initial bank will have a higher oil saturation and lower water saturation than the injected bank. Each bank will also have different fractional flows of each component. The fractional flow of a component is the fraction of the total flow that the component comprises. For example if the 40% of the total volumetric flow of fluids is water, then the fractional flow of water is 0.4. The fractional flow of a component is also known as the cut of that component when it is being measured at the producer (Walsh and Lake 2003).

In the simple case, the oil cut at the producer will remain constant until the displacing fluid, the injected bank, arrives, at which point the oil cut will experience a step change. This type of behavior is captured with the equations

$$f_o(t_D) = \begin{cases} f_{oI} & t_D < \frac{1}{v_{disp}} \\ f_{oF} & t_D > \frac{1}{v_{disp}} \end{cases}$$

**Equation 3-1**

where  $f_o(t_D)$  is the oil cut at a given time,  $f_{oI}$  and  $f_{oF}$  are the oil cut for the initial and injected banks, respectively, and  $v_{disp}$  is the specific shock velocity of the displacing fluid

front, and  $t_D$  is dimensionless time. The specific shock velocity is a dimensionless velocity that describes the relative velocity of the front of a bank. The dimensionless time is in terms of injected total pore volumes of the reservoir. Equation 3-1 can also be written as

$$f_o = f_{oI} + (f_{oF} - f_{oI})F(t_D)$$

**Equation 3-2**

where  $F(t_D)$  is a set of step equations that describe the fractional flow of the displacing component as follows

$$F(t_D) = \begin{cases} 0 & t_D < \frac{1}{v_{disp}} \\ 1 & t_D > \frac{1}{v_{disp}} \end{cases}$$

**Equation 3-3**

### **3.2.2 Description of the Simple Case for an EOR Flood**

The previous example can be extended to apply to a simple and ideal EOR flood. It is assumed that upon injection of the chemicals, the reservoir would begin to form three distinct banks, because of newly mobilized oil within the reservoir. The first bank represents the initial condition that existed before the flood. The second bank consists of oil released from previously trapped oil that is mobilized by the injected chemicals. The injected bank represents the injected chemicals. All previous assumptions continue to be applied. Figure 3-2 is a diagram of the piston-like case for an EOR flood.

**Figure 3-2 Profile of a Snap Shot in Time of a One Dimensional Flow for a Piston Like Three Bank Flow**

There are two fronts, one for the bank of mobilized oil and another for the injected chemicals. Again, there is constant oil saturation and fractional flow of oil within each section. Before the oil bank reaches the producer, the producer will continue to behave as it did during the previous production by holding a constant oil cut. Once the oil bank reaches the producer, a shock occurs in the oil cut and it would again remain constant until the injected fluid reaches the producer. Figure 3-3 is a plot of how the oil cut will behave under these ideal conditions.

**Figure 3-3 Oil Cut for a Three Bank Piston Like Flow**

The oil cut experienced over the life of the flood can be expressed as step equations in terms  $t_D$

$$f_o(t_D) = \begin{cases} f_{oI} & 1 < v_{oB}t_D \\ f_{oB} & v_{oB}t_D < 1 < v_Ct_D \\ f_{oF} & 1 > v_Ct_D \end{cases}$$

**Equation 3-4**

where  $f_{oB}$  is the oil cut for the oil bank,  $v_{oB}$  is the specific shock velocity of the oil bank, and  $v_C$  is the specific shock velocity of the injected bank. The oil cut is assumed to be zero when the injected fluid reaches the producer because the piston model assumes perfect displacement of all mobilized oil in the system. Equation 3-4 can also be written as

$$f_o(t_D) = f_{oI} + (f_{oB} - f_{oI})F_{oB}(t_D) + (f_{oF} - f_{oB})F_{oF}(t_D)$$

**Equation 3-5**

where  $F_{oB}(t_D)$  is the fractional flow of the oil bank and is described by the step equations

$$F_{oB}(t_D) = \begin{cases} 0 & t_D < \frac{1}{v_{oB}} \\ 1 & t_D > \frac{1}{v_{oB}} \end{cases}$$

**Equation 3-6**

and  $F_{oF}(t_D)$  is the fractional flow of the injected fluids as described by similar step equations

$$F_{oF}(t_D) = \begin{cases} 0 & t_D < \frac{1}{v_C} \\ 1 & t_D > \frac{1}{v_C} \end{cases}$$

Equation 3-7

### 3.3 The Actual Condition with Two Banks

The piston model does not accurately represent actual flow due to channeling caused by the heterogeneity of the reservoir and relatively large mobility ratio between the oil and the injected chemicals. Channeling occurs when the majority of the displacing fluid follows a path of least resistance through the medium between the injector and producer, preventing even displacement of the original in-place fluids. Hence, there is no instantaneous rise or fall in oil cut and the flow of the oil is not simply characterized by the velocity of the injected bank front. Figure 3-4 is a generic profile representing the more realistic condition with a two component flow. Figure 3-5 is a plot of the oil cut against time for a heterogeneous two bank system for a water flood.

Figure 3-4 Profile of a Snap Shot in Time of a Generic for a Two Bank Flow with Channeling

Figure 3-5 Oil Cut against Time for a Heterogeneous Two Bank Flow

### 3.4 The Actual Condition with Three Banks

Figure 3-6 is a generic profile for an EOR flood. It is still assumed that upon injection of the chemicals, three distinct banks will form within the reservoir and that the fractional flow theory continues to apply locally. The oil bank will also experience channeling because of the heterogeneity of the medium and the mobility between the fluids in the system.

Figure 3-6 Profile of Generic for a Three Bank Flow with Channeling

The producer will continue to experience an oil cut similar to the one experienced during water flooding until the tip of the oil bank, point “A,” reaches the producer. Then the producer will begin to experience a gradual rise in oil cut until the most advanced point of the injected chemicals, point “B”, reaches the producer. The producer will then experience either a decline in oil cut or a more gradual rise in oil cut and then begin to decline. Figure 3-7 is a typical oil cut against time plot for a reservoir.

Figure 3-7 Oil Cut for a Three Component Flow with Channeling

Equation 3-6 and Equation 3-7 can be altered to account for less shock-like changes in fractional flow by adding an intermediate step that is defined by a variable that captures the channeling,  $C$ , as follows

$$F(t_D) = \begin{cases} 0 & F_{\text{disp}}(C, t_D) < 0 \\ F_{\text{disp}}(C, t_D) & 0 > F_{\text{disp}}(C, t_D) > 1 \\ 1 & F_{\text{disp}}(C, t_D) > 1 \end{cases}$$

Equation 3-8

### 3.5 Predicting Frontal Velocities

Pope (1980) noted that the specific velocity of a front for isothermal recovery methods can be found through the application of fractional flow theory. Equations were

developed as means to estimate the specific velocities of the two assumed fronts during an EOR flood.

### 3.5.1 Application of the Conservation of Mass

The law of the conservation of mass is used as a starting point in relating saturation and the fractional flow of a fluid. Buckley and Leverett (1942) showed from material balance that the equation for the conservation of a displacing fluid is

$$\frac{\partial S_{\text{disp}}}{\partial t} + u_{\text{disp}} \frac{\partial F_{\text{disp}}}{\partial x} = 0$$

**Equation 3-9**

where  $t$  is time,  $x$  is the distance from the injector,  $S_{\text{disp}}$  is the saturation of the displacing fluid,  $F_{\text{disp}}$  is the fractional flow of the displacing fluid, and  $u_{\text{disp}}$  is the interstitial velocity for the displacing fluid as defined by the following

$$u_{\text{disp}} = \frac{q}{A\phi}$$

**Equation 3-10**

where  $q$  is volumetric flow,  $A$  is cross sectional area, and  $\phi$  is porosity. The interstitial velocity is the average velocity of a fluid's front.

To help make the equation applicable with any size media, dimensionless units are used in place of  $t$  and  $x$ . The relative distance,  $x_D$ , is

$$x_D(x) = \frac{\int_0^x A\phi d\xi}{\int_0^L A\phi d\xi} = \frac{\text{Volume of pores filled by injected slug}}{\text{Total volume of pores}}$$

**Equation 3-11**

where  $L$  is the distance between the injector and producer. If  $\phi$  and  $A$  are constant throughout the reservoir, then there is the special case

$$x_D(x) = \frac{x}{L}$$

**Equation 3-12**

The value for  $x$  equals zero at the injector, and  $L$  at the producer. Dimensionless time,  $t_D$ , is the total volume of injected fluid up to time  $t$  divided by the total pore volume of the medium, as shown

$$t_D(t) = \frac{\int_0^t q d\xi}{\int_0^L A\phi d\xi} = \frac{\text{Injected volume}}{\text{Total pore volume}}$$

**Equation 3-13**

For the special case that  $\phi$  and  $A$  are constant throughout the reservoir Equation 3-13 becomes

$$t_D(t) = \frac{qt}{A\phi L} = \frac{qt}{V_p}$$

**Equation 3-14**

where  $V_p$  is the total pore volume of the system.

Taking the derivatives of Equation 3-12 and Equation 3-14 produces

$$dx_D = \frac{dx}{L}$$

**Equation 3-15**

$$dt_D = \frac{qdt}{V_p}$$

**Equation 3-16**

Substitutions of Equation 3-10, Equation 3-15, and Equation 3-16 into Equation 3-9 yields

$$\frac{\partial S_{\text{disp}}}{\partial t_D} + \frac{\partial F_{\text{disp}}}{\partial x_D} = 0$$

**Equation 3-17**

This equation demonstrates a correlation between saturation and fractional flow in dimensionless terms.

### **3.5.2 Application of the Frontal Advance Formula**

Buckley and Leverett (1942) determined the frontal advance formula by transforming the material balance equation, Equation 3-9, into the following form

$$J_{\text{disp}} = \frac{q}{A\phi} \frac{dF_{\text{disp}}}{dS_{\text{disp}}}$$

**Equation 3-18**

where  $J_{\text{disp}}$  is the saturation velocity, which is a dimensional velocity of the constant saturation front. Similarly, Equation 3-17 can be transformed to

$$v_{\text{disp}} = \frac{dx_D}{dt_D} = \frac{dF_{\text{disp}}}{dS_{\text{disp}}}$$

**Equation 3-19**

where  $v_{\text{disp}}$  is the specific shock velocity of the displacing front. The specific shock velocity is the dimensionless form of the saturation velocity.

### 3.5.3 Application of the Fractional Flow Curve for the Surfactant-Polymer and Alkali-Surfactant-Polymer Cases

The discussion for this section focuses on the construction and application of the fractional flow curves for SP and ASP floods.

To determine the fractional flow of the displacing fluid for different times and parts of the flood, a fractional flow curve is implemented. According to Buckley and Leverett (1942), if gravity effects and capillary pressure differences are neglected, then the fractional flow of the displacing chemicals is described by

$$F_w = \frac{1}{1 + \frac{k_{ro} \mu_w}{k_{rw} \mu_o}}$$

**Equation 3-20**

where  $F_w$  is the fractional flow of the injected water,  $k_{ro}$  and  $k_{rw}$  represent the relative permeability of oil and the injected water, respectively, and  $\mu_o$  and  $\mu_w$  are the viscosities of the oil and the injected water, respectively.

As the displacing fluids move from a highly water saturated region to a lower one, oil is removed, reducing the oil saturation and increasing the displacing fluid concentration. As a result, the permeability of both the oil and displacing fluid change and the permeability values are a function of the saturation of the displacing fluid (Buckley and Leverett 1942). Corey-type equations help define this relationship through the functions (Brooks and Corey, 1966).

$$k_{rw} = k_{rw}^0 (S)^n$$

$$k_{ro} = k_{ro}^0 (1 - S)^m$$

**Equation 3-21**

where  $k_{rw}^0$  and  $k_{ro}^0$  are end-point relative permeability values for water and oil respectively,  $m$  and  $n$  are constants that characterize the functions, and  $S$  is the relative saturation of the system.  $S$  is defined by the equation

$$S = \frac{S_w - S_{wr}}{1 - S_{or} - S_{wr}}$$

**Equation 3-22**

where  $S_w$  is the water saturation,  $S_{wr}$  and  $S_{or}$  are the residual saturations of the displacing fluid and oil, respectively. Figure 3-8 is a plot of generic relative permeability curves based on properties from Table 3-1.

**Figure 3-8 Generic Relative Permeability Curves**

Substituting Equation 3-20 into Equation 3-21 yields

$$F_w = \frac{1}{1 + \frac{k_{ro}^o(1-S)^m \mu_w}{k_{rw}^o(S)^n \mu_o}}$$

**Equation 3-23**

Figure 3-9 is a generic plot for a fractional flow curve as defined by the parameters in Table 3-1. The curve is a typical example of a water flood. The fractional flow is in terms of water cut because it is assumed the measurement is being made at the producer.

**Figure 3-9 Generic Fractional Flow Curve Based on Values in Table 3-1**

**Table 3-1: Summary of Input Values for the General Fractional Flow Curve**

Input	Variable	Value	Units
Viscosity of water	$\mu_w$	1	cp
Viscosity of oil	$\mu_o$	5	cp
End point relative permeability of water	$k_{rw}^o$	0.2	--
End point relative permeability of oil	$k_{ro}^o$	0.8	--
Corey type exponent for water	$n$	2	--
Corey type exponent for oil	$m$	2	--
Residual water saturation	$S_{wr}$	0.2	--
Residual oil saturation	$S_{or}$	0.25	--

Based on Equation 3-19, the curve predicts the specific velocities for different saturation fronts of various types of floods.

The simplest case is a water flood. The velocity of a continuous saturation front is defined as the slope of the fractional curve at a given saturation. At some saturation there is a maximum velocity. If the initial saturation is lower than the maximum, then that would suggest that upstream saturations fronts are travelling at faster rate than the downstream fronts, which creates situations where the slower velocity fronts are overtaken. Therefore, multiple saturations would exist at one point. This does not happen in nature because a shock front forms. The specific shock velocity is defined as the slope of a line between the initial condition for the flood, I, and a point tangent to the fractional flow curve, known as the saturation point, Z. Between the saturation point and the final condition point, J, the specific shock velocity decreases, creating a gradual change in the fractional flow of water over time. Figure 3-10 is a fractional flow curve demonstrating how the specific shock velocity for a water flood is estimated. Figure 3-11 is the saturation profile for the example water flood at  $t_D$  equals  $0.3 V_P$ .

Figure 3-10 Fractional Flow Curve with Specific Shock Velocity for a Water Flood (Lake 1989)

Figure 3-11 Approximation of the Saturation Profile for the Example Water Flood

An EOR process involves the formation of an oil bank and the injection of chemicals with significantly different properties than the in-situ oil or brine. Careful attention is required to calculate the specific velocities of the bank and injected chemicals.

Two fractional flow curves are necessary to capture the EOR process. The first is oil and water curve, similar to Figure 3-10. This curve is used to capture how the oil bank will displace the initial in place fluids. The second curve is for the displacing agent and oil and it is used to capture how the bank is displaced by the injected displacing agents. Figure 3-12 is a schematic plot of the two curves with the critical points marked.

For each curve, the points that define the specific velocities are the initial and final conditions. The arrows show how the saturations and fractional flow change over time. The specific shock velocity for the bank is no longer tangent to the curve as for the water flood; the specific shock velocity will only decrease between the initial and final condition, as the highest velocity for the displacing fluid exists where the lowest saturation exists. Therefore, in the special case where the oil bank is the displacing fluid and has a higher oil saturation than the displaced fluid, typically only one specific shock velocity is expected to exist. See Lake (1989, Chapter 5) for more details and background about the construction of fractional flow curves.

45

Figure 3-13. The assumptions create minor changes for  $v_{oB}$  and  $v_C$ ; however the sensitivity analysis (Chapter 5) shows them to be relatively insignificant.

**Figure 3-13 Simplified Fractional Flow Curves for a Generic EOR Scenario**

From Equation 3-19 and the simplifying assumptions for fractional flow behavior, the specific velocities of both the oil bank and the injected chemical fronts can be captured by

$$v_{disp} = \frac{F_{disp|F} - F_{disp|I}}{S_{disp|F} - S_{disp|I}}$$

**Equation 3-24**

where the subscripts I, and F refer to initial and final condition, respectively. For the oil bank

$$F_{\text{disp|F}} = 1 - f_{\text{oB}}$$

$$F_{\text{disp|I}} = 1 - f_{\text{oI}}$$

$$S_{\text{disp|F}} = 1 - S_{\text{oB}}$$

$$S_{\text{disp|I}} = 1 - S_{\text{oI}}$$

**Equation 3-25**

where the subscripts “oB” refer to the oil bank and “oI” refer to the oil saturation at the initial in-situ condition. Oil cuts are used instead of fractional flow of oil at a certain  $x_D$  because what occurs at the producer is most important. Therefore  $v_{\text{oB}}$  equals

$$v_{\text{oB}} = \frac{f_{\text{oB}} - f_{\text{oI}}}{S_{\text{oB}} - S_{\text{oI}}}$$

**Equation 3-26**

Similarly for the injected chemicals

$$F_{\text{disp|F}} = 1$$

$$F_{\text{disp|I}} = 0$$

$$S_{\text{disp|F}} = 1 - S_{\text{oF}}$$

$$S_{\text{disp|I}} = 0$$

**Equation 3-27**

where  $S_{\text{oF}}$  is the EOR flood residual oil saturation at the end of the flood. Therefore  $v_C$  equals

$$v_C = \frac{1}{1 - S_{oF}}$$

**Equation 3-28**

The line for  $v_C$  also must pass through the bank condition because the injected chemical will displace the bank as well. Therefore, the following is also true

$$F_{\text{disp|F}} = 1$$

$$F_{\text{disp|I}} = 1 - f_{oB}$$

$$S_{\text{disp|F}} = 1 - S_{oF}$$

$$S_{\text{disp|I}} = 1 - S_{oB}$$

**Equation 3-29**

and

$$v_C = \frac{f_{oB}}{S_{oB} - S_{oF}}$$

**Equation 3-30**

Figure 3-14 is the saturation profile for the simplified case represented by the fractional flow curves in Figure 3-13.

**Figure 3-14 Oil Saturation Profile of the Simplified Fractional Flow Curves for the Generic EOR Scenario**

Referring to Equation 3-5, Equation 3-26, and Equation 3-30, several variables are necessary to produce a prediction. Based on the history of the flood and core data,  $f_{oI}$  and  $S_{oI}$  may be estimated. The properties of the oil bank and  $S_{oF}$  are the remaining unknowns.  $S_{oF}$  captures the amount of oil recovered from the flood, where the lower  $S_{oF}$  is, the better the recovery. Hence it is a value that is not easily known. As for finding the properties of the oil bank, one must determine whether to assume values for  $f_{oB}$  and  $S_{oB}$  or to make assumptions about  $v_{oB}$  and  $v_C$ . From Figure 3-13, the line representing  $v_{oB}$  must go through both the points representing the initial conditions at the start of the flood and the oil bank, as it is these two points that define the slope. The line representing  $v_C$  must also go through the points representing the origin, oil bank and final condition,  $S_{oF}$ . Therefore, there are three critical points needed to define the two frontal velocities; however, the only point known with any confidence is the initial condition point. The

point representing the bank can be found from the intersection of the  $v_C$  line and the bank's fractional flow curve (relative permeability values and viscosities). Ultimately, this suggests that with a known fractional flow curve for the oil bank and assumed final oil saturation at the end of the flood, one could determine the specific velocities and the properties of the bank.

#### **3.5.4 Application of the Fractional Flow Curve for the CO<sub>2</sub> Flood Case**

The discussion for this section focuses on the construction and application of the fractional flow curves for CO<sub>2</sub> floods. The behavior of CO<sub>2</sub> flooding is different from other miscible processes because the CO<sub>2</sub> has appreciable solubility into both oil and water (Pope 1980). Therefore the construction is altered, in particular the construction for the line representing the specific shock velocity of the injected CO<sub>2</sub> solvent.

Walsh and Lake (1988) created a method to apply fractional flow theory to solvent flooding. The theories and assumptions made for SP and ASP cases continue to apply. Once again two curves are required for determining the fractional flow velocities of the oil bank and the chasing solvent. One curve is the oil and water curve and the other is solvent and water curve. Both curves are constructed with the same parameters, except different viscosities. For the solvent and water curve the viscosity of the solvent is used in place of the oil. Table 3-2 is a summary of generic parameters used to create generic oil and water, and solvent and water fractional flow curves shown in Figure 3-15.

**Table 3-2 Summary of the Input Values for the General Oil and Water and Solvent, and Water**

**Fractional Flow Curves**

Input	Variable	Value	Units
Viscosity of water	$\mu_w$	1	cp
Viscosity of oil	$\mu_o$	1.5	cp
Viscosity of solvent	$\mu_s$	0.07	cp
End point relative permeability of water	$k_{rw}^o$	0.2	--
End point relative permeability of oil	$k_{ro}^o$	0.8	--
Corey type exponent for water	n	2	--
Corey type exponent for oil	m	2	--
Residual water saturation	$S_{wr}$	0.2	--
Residual oil saturation	$S_{or}$	0.4	--

**Figure 3-15 Generic Fractional Flow Curves Based on Values in Table 3-2**

CO<sub>2</sub> flooding involves injecting water with CO<sub>2</sub> as a means to improve the mobility between the solvent and oil. This process is done by either alternating injection of water solvent or by mixing the two together. The ratio of water to gas is known as the WAG ratio and it based on volume. The WAG ratio is a design parameter and it is important parameter for determining the specific shock velocity of the fractional flow of the solvent. Walsh and Lake determined that the WAG ratio controls the fractional flow of water at the injector end at the beginning of the flood,  $f_{wJ}$ , with the following relationship

$$f_{wJ} = \frac{WAG}{1 + WAG}$$

**Equation 3-31**

The line representing the specific shock velocity of the solvent passes through a point on the solvent and water curve at  $f_{wJ}$ . The line also passes through the point where the line for the specific shock velocity of the oil passes through the oil and water curve. The specific shock velocity of the solvent is  $v_C$  and the specific shock velocity of the oil bank is  $v_{oB}$ . The line for  $v_C$  also passes through the point representing the final oil saturation,  $S_{oF}$ , at the end of the flood. Figure 3-16 is a plot of the fractional flow curves and the specific shock velocities. A line could be used to approximate the solvent and water curve.

Figure 3-16 is very similar to Figure 3-13. The most significant difference is with the line for  $v_C$ . For SP and ASP floods the line is anchored in at the origin and for CO<sub>2</sub> it is anchored into a point along the solvent and water curve at a point designated by the WAG ratio.

See Walsh and Lake (1988) for more details and background about the construction of fractional flow curves for solvent flooding.

**Figure 3-16 Generic Fractional Flow Curve CO<sub>2</sub> Floods**

Equation 3-26 and Equation 3-30 can be used to calculate  $v_{oB}$  and  $v_c$ , respectively. If the WAG ratio and the properties of the fractional flow curves are known or assumed then the location and value of  $f_{wJ}$  is known. With that information Equation 3-30 can also be defined as

$$v_c = \frac{f_{wJ}}{S_{wJ} - S_{oF}}$$

**Equation 3-32**

where  $S_{wJ}$  is the water saturation at  $f_{wJ}$ . With  $v_C$  known, the starting point for the line for  $v_{oB}$  defined by the properties at the start of tertiary flooding, the oil and water curve known, then  $v_{oB}$  can be determined. Also with  $v_C$  known,  $S_{oF}$  can be determined. Therefore, with information about the fractional flow curves and the WAG ratio, the specific shock velocities and the final oil saturation can be determined.

### **3.6 Koval's Method**

Koval (1963) attempted to capture the behavior of an unstable miscible flood through simple equations called Koval's method. The method is centered on the concept that heterogeneity and mobility of the fluids can be captured under one variable, a Koval factor, which is used to describe bypassing or channeling.

#### **3.6.1 Koval's Assumptions**

The method follows similar assumptions as mentioned before and includes that the solvent is miscible with the oil in place and the fractional flow curve is simplified. It is based on fractional flow curves that go from  $S_{disp}=0$  and  $F_{disp}=0$  to  $S_{disp}=1$  and  $F_{disp}=1$ . This approach suggests that all of the fluid in the system is mobilized. Furthermore the method is based on the Buckley-Leverett theory and material balance (Koval, 1963).

#### **3.6.2 Development of Koval's Equations**

The Buckley-Leverett theory provides two critical relationships, the frontal advance formula, and the fractional flow equation. Koval's method begins with the fractional flow equation as shown in Equation 3-20 and, based on the assumption of

locally segregated flow between the solvent and oil, the interaction between the oil and the displacing fluid can be determined the following relationships

$$k_{rdisp} = k^o(S_{disp})$$

$$k_{ro} = k^o(1 - S_{disp})$$

**Equation 3-33**

where  $k$  is permeability,  $k_{rdisp}$  is the relative permeability of the displacing fluid and  $S_{disp}$  is the displacing fluid saturation. Equation 3-33 is the Corey-type assumption, Equation 3-21, with  $m = n = 1$ . Koval assumed that there was considerable evidence to suggest that a heterogeneity factor,  $H$ , and effective viscosity ratio,  $E$ , are critical to the recovery of oil. The Koval factor,  $K_{disp}$ , is defined as the product of the heterogeneity factor and effective viscosity ratio. The effective viscosity can be estimated with the following

$$E = \left(0.78 + 0.22v^{\frac{1}{4}}\right)^4$$

**Equation 3-34**

where  $E$  is the effective viscosity and  $v$  is  $\mu_o/\mu_{disp}$ . The heterogeneity factor is a value estimated based on experimental data.

Substitution of Equation 3-33 into Equation 3-20 and following his assumptions, Koval determined that

$$F_{\text{disp}} = \frac{1}{1 + \frac{(1 - S_{\text{disp}})}{(S_{\text{disp}})} \frac{1}{K_{\text{disp}}}}$$

**Equation 3-35**

Figure 3-17 is a plot showing various ranges of fractional flow curves as they apply to the Koval method. Note that the displacing fluid has an initial condition of zero saturation and flow and final condition of 100% saturation and flow.

**Figure 3-17 Range of Fractional Flow Curves for the Koval Method**

Referring back to the frontal advance formula, Equation 3-19, and by taking the derivative of Equation 3-35 in terms of S, it is found that

$$\frac{dF_{\text{disp}}}{dS_{\text{disp}}} = \frac{dx_D}{dt_D} = \frac{K_{\text{disp}}}{[1 + (K_{\text{disp}} - 1)S_{\text{disp}}]^2}$$

**Equation 3-36**

By taking Equation 3-35 and setting it equal to  $S_{\text{disp}}$ , substituting it back into Equation 3-36, and then applying it to Equation 3-8, Koval developed the following set of simple equations designed to capture the behavior of the fractional flow of the displacing fluid

$$F_{\text{disp}}(x_D, t_D) = \begin{cases} 0 & t_D < \frac{x_D}{K_{\text{disp}}} \\ \frac{K_{\text{disp}} - \sqrt{\frac{K_{\text{disp}} x_D}{t_D}}}{(K_{\text{disp}} - 1)} & \frac{x_D}{K_{\text{disp}}} < t_D < x_D K_{\text{disp}} \\ 1 & t_D > x_D K_{\text{disp}} \end{cases}$$

**Equation 3-37**

Figure 3-18 is a collection of water cut curves for various  $K$  values. Higher  $K$  values imply higher heterogeneity of the medium.

**Figure 3-18 Example of Fractional Flow of Water Curves for Various Koval Factors**

Koval's model worked with two bank flow; therefore  $f_o$  is

$$F_o(x_D, t_D) = 1 - F_{\text{disp}}(x_D, t_D)$$

**Equation 3-38**

For more details refer to Koval (1963).

### **3.7 Development of the Simplified Enhanced Oil Recovery Model**

The simplified enhanced oil recovery method (SEORM) has Koval's model as its foundation. SEORM is designed to maintain the simplicity of Koval's method, while still addressing its short comings as discussed in Chapter 2.

#### **3.7.1 Derivation of the Fractional Flow Equation for the Simplified Enhanced Oil**

##### **Recovery Method**

The Koval model essentially works with a two component flow for moveable pore volume is the same as pore volume. The first step in building SOERM is to use the Koval model as a starting point with Equation 3-36. Up to this point the total pore volume was assumed to also be the sweepable pore volume at any time during the flood. This is not the case typically as residual saturations will prevent complete sweep of the total pore volume. Therefore the frontal advance formula is redefined as

$$\frac{dF_{\text{disp}}}{dS_{\text{disp}}} = \frac{x_D}{t_{D|s}}$$

**Equation 3-39**

where  $t_{D|s}$  is dimensionless time in terms of sweepable pore volume defined as

$$t_{D|s} = \frac{tq(\Delta F_{\text{disp}})}{V_p(\Delta S_{\text{disp}})}$$

**Equation 3-40**

The change in fractional flow of the displacing fluid,  $\Delta F_{\text{disp}}$ , refers to the change that occurs between banks. The injection rate,  $q$ , multiplied by the change in fractional flow expresses the amount of the injected fluid that is moving through the sweepable pore volume, which captures the change in rate through the sweepable pore volume. The total pore volume,  $V_p$ , multiplied by the change in saturation represents the change in sweepable pore volume.

From Equation 3-40,  $t_{D|s}$  is the product of  $t_D$  and the specific shock velocity of the displacing fluid,  $v_{\text{disp}}$ . Thus, Equation 3-36 becomes

$$\frac{dF_{\text{disp}}}{dS_{\text{disp}}} = \frac{dx_D}{dv_{\text{disp}}t_D} = \frac{K_{\text{disp}}}{[1 + (K_{\text{disp}} - 1)S_{\text{disp}}]^2}$$

**Equation 3-41**

Equation 3-41 is then set equal to  $S_{\text{disp}}$  and then substituted into Equation 3-35 to get

$$F_{\text{disp}}(x_D, t_D) = \frac{K_{\text{disp}} \sqrt{\frac{t_D V_{\text{disp}}}{K_{\text{disp}} x_D} - 1}}{(K_{\text{disp}} - 1) \sqrt{\frac{t_D V_{\text{disp}}}{K_{\text{disp}} x_D}}}$$

**Equation 3-42**

### 3.7.2 Derivation of the Oil Cut Equation

Recall that Equation 3-5 captures the oil cut for an ideal three component case. With Equation 3-42 as the definition for the change in fractional flow of the displacing fluid in Equation 3-8, Equation 3-42 becomes

$$F_{\text{disp}}(x_D, t_D) = \begin{cases} 0 & t_D < \frac{x_D}{K_{\text{disp}} v_{\text{disp}}} \\ \frac{K_{\text{disp}} \sqrt{\frac{t_D v_{\text{disp}}}{K_{\text{disp}} x_D}} - 1}{(K_{\text{disp}} - 1) \sqrt{\frac{t_D v_{\text{disp}}}{K_{\text{disp}} x_D}}} & \frac{x_D}{K_{\text{disp}} v_{\text{disp}}} < t_D < \frac{x_D K_{\text{disp}}}{v_{\text{disp}}} \\ 1 & \frac{x_D K_{\text{disp}}}{v_{\text{disp}}} > t_D \end{cases}$$

**Equation 3-43**

Note how the limits for each step are now defined. As Equation 3-43 is applied to the oil bank component it becomes

$$F_{\text{oB}}(x_D, t_D) = \begin{cases} 0 & t_D < \frac{x_D}{K_1 v_{\text{oB}}} \\ \frac{K_1 \sqrt{\frac{t_D v_{\text{oB}}}{K_1 x_D}} - 1}{(K_1 - 1) \sqrt{\frac{t_D v_{\text{oB}}}{K_1 x_D}}} & \frac{x_D}{K_1 v_{\text{oB}}} < t_D < \frac{x_D K_1}{v_{\text{oB}}} \\ 1 & t_D > \frac{x_D K_1}{v_{\text{oB}}} \end{cases}$$

**Equation 3-44**

where  $K_1$  is the Koval factor for the flow between the oil and initial banks. Similarly for the injected chemical component, Equation 3-43 becomes

$$F_{oF}(x_D, t_D) = \begin{cases} 0 & t_D < \frac{x_D}{K_2 v_c} \\ \frac{K_2 \sqrt{\frac{t_D v_c}{K_2 x_D}} - 1}{(K_2 - 1) \sqrt{\frac{t_D v_c}{K_2 x_D}}} & \frac{x_D}{K_2 v_c} < t_D < \frac{x_D K_1}{v_c} \\ 1 & t_D > \frac{x_D K_2}{v_c} \end{cases}$$

**Equation 3-45**

where  $K_2$  is the Koval factor for the flow between the injected and oil banks. Equation 3-5 still applies as mentioned earlier.

### **3.7.3 Summary of Critical Equations for the Simplified Enhanced Oil Recovery**

#### **Method**

The following equations are summarized for SEORM. To simplify the equations slightly, it is assumed that the main concern for a flood is how the producers react during the EOR process; therefore,  $x_D$  is set to equal one so that the equations describe the behavior of the flood at the producers.

$$f_o(t_D) = f_{oI} + (f_{oB} - f_{oI})F_{oB}(t_D) + (f_{oF} - f_{oB})F_{oF}(t_D)$$

**Equation 3-46**

$$F_{oB}(t_D) = \begin{cases} 0 & t_D < \frac{1}{K_1 v_{oB}} \\ \frac{K_1 \sqrt{\frac{t_D v_{oB}}{K_1}} - 1}{(K_1 - 1) \sqrt{\frac{t_D v_{oB}}{K_1}}} & \frac{1}{K_1 v_{oB}} < t_D < \frac{K_1}{v_{oB}} \\ 1 & t_D > \frac{K_1}{v_{oB}} \end{cases}$$

**Equation 3-47**

$$F_{oF}(t_D) = \begin{cases} 0 & t_D < \frac{1}{K_2 v_C} \\ \frac{K_2 \sqrt{\frac{t_D v_C}{K_2}} - 1}{(K_2 - 1) \sqrt{\frac{t_D v_C}{K_2}}} & \frac{1}{K_2 v_C} < t_D < \frac{K_2}{v_C} \\ 1 & t_D > \frac{K_2}{v_C} \end{cases}$$

**Equation 3-48**

$$v_{oB} = \frac{f_{oB} - f_{oI}}{S_{oB} - S_{oI}}$$

**Equation 3-49**

$$v_C = \frac{1}{1 - S_{oF}} = \frac{1 - f_{oB}}{1 - S_{oB}}$$

**Equation 3-50**

Figure 3-19 is a typical plot of SEORM. The rise and decline of the oil cut are captured by the cumulative sum of the changes in  $F_{oB}(t_D)$  and  $F_{oF}(t_D)$ , as described in

Equation 3-47 and Equation 3-48. Note the close resemblance to the expected behavior of the actual case for an EOR flood.

Figure 3-19 Example of SEORM Predicting Oil Cut

### 3.7.4 Discussion of the Input Parameters for the Simplified Enhanced Oil Recovery

#### Method

Table 3-3 summarizes the input variables for Equation 3-46 through Equation 3-50.

**Table 3-3 Summary of Input Parameters for SEORM**

<b>Input Parameter</b>	<b>Description</b>
$t_D$	Dimensionless time in terms of injected pore volume
$f_{oI}$	Oil cut at start of EOR flood
$f_{oB}$	Peak oil cut for mobilized oil bank
$f_{oF}$	Oil cut at the end of EOR flood, assumed to be zero
$S_{oI}$	Average oil saturation at the start of EOR flood
$S_{oB}$	Oil saturation within the mobilized oil bank
$S_{oF}$	Average oil saturation at the end of the EOR flood
$K_1$	The Koval factor for the flow between the mobilized oil and initial banks
$K_2$	The Koval factor for the flow between the injected and mobilized oil banks
$v_{oB}$	The specific shock velocity of the mobilized oil bank
$v_C$	The specific shock velocity of the injected chemical bank
WAG	The WAG ratio, applies only to CO <sub>2</sub> flooding

Of the 12 inputs listed in Table 3-3, eight must be input by the user:  $f_{oI}$ ,  $f_{oF}$ ,  $S_{oI}$ ,  $S_{oF}$ ,  $K_1$ ,  $K_2$ ,  $v_{oB}$ , and WAG. Of the eight user inputs, only three have considerable uncertainty.

The values for  $f_{oI}$  and  $S_{oI}$  are usually estimated based on careful observation from previous recovery methods. Also,  $f_{oF}$  is typically assumed to be zero because under normal circumstances it would be a small value ranging between zero and one percent. Oil cuts within this low range are typically uneconomical to recover and therefore, can be neglected.

The parameter WAG is a design parameter and may be well understood; however, the actual water to solvent ratio that may exist during the flood could be different from what was intended. Therefore, there may be some uncertainty with WAG.

The parameters  $f_{oB}$ ,  $S_{oB}$ ,  $v_{oB}$ , and  $v_C$  can all be calculated from the fractional flow curve with an assumed value for  $S_{oF}$  or WAG, depending on the type of flood. If no

fractional flow curve is available, then  $v_{oB}$  is used as an input parameter because this value is a strong reflection of the fractional flow curve; however, the uncertainty in  $f_{oB}$  and  $S_{oB}$  then becomes a function of  $v_{oB}$ . The final three parameters,  $K_1$ ,  $K_2$ , and  $S_{oF}$  contain significant meaning as they each capture special aspects of the behavior of an EOR flood.

The Koval factors,  $K_1$  and  $K_2$ , are direct reflections of the magnitude of the heterogeneity of the reservoir, the mobility between displacing and displaced fluids, and adsorption of injected chemical. Overall, the Koval factors are indicators of the effectiveness of the flood's sweep through the mobilized fluids. Small values insinuate that the sweep is efficient, for example  $K$  values equal to one represent an ideal sweep similar to the piston like condition as shown in Figure 3-2 and Figure 3-3. Larger values of  $K$  imply that the flood has significant channeling and it is likely that the mobilizing agent in the injected bank, such as polymer, had considerable adsorption into the media. These effects reduce sweep efficiency and create longer floods with lower peak oil cuts. Furthermore,  $K_1$  and  $K_2$  are independent with certain limitations.  $K_2$  cannot exceed a certain values that would cause the appearance that the injected bank breaks through before the oil bank. Equation 3-51 defines the upper limit for  $K_2$ .

$$K_{2|_{\max}} = \frac{K_1 v_{oB}}{v_C}$$

**Equation 3-51**

A situation where the injected bank breaks through before the oil bank can technically occur; however, the model is unable to handle such a situation and creates an error. Also,  $K_1$  or  $K_2$  cannot be less than one because a value of one represents the piston condition.

The parameter  $S_{oF}$  is a strong reflection of how effective the injected chemicals are at mobilizing the residual oil in the reservoir. Small values indicate efficient recovery of the residual oil. A large value may imply poor recovery because of a low injected agent volume, lost chemical, poor contact between the mobilizing agent and the residual oil, or deterioration or absorption of the agent into the media.  $S_{oF}$  also somewhat reflects the total pore volumes of the reservoir. For example a high  $S_{oF}$  may mean the sweep volume is overestimated.

### **3.7.5 Discussion of Other Important Parameters for the Simplified Enhanced Oil Recovery Method**

There are a couple of other inputs for SEORM that are not directly part of the equations; however, they do influence the prediction. The first is the total pore volume of the reservoir,  $V_p$ . The assumed  $V_p$  alters various attributes of the floods such as the scale of the dimensional time axis and the total recovered volume of oil. A large  $V_p$  value means that the reservoir is large and requires a higher volume of chemical agents for the flood to be effective. Furthermore, a large  $V_p$  value suggests it would take a longer time to flood the reservoir and see a change in oil cut. Assuming that the original prediction for the oil saturation of the reservoir is accurate, the volume of recovered oil is directly proportional to  $V_p$ .

Other critical input parameters are the expected injection rate for the life of the flood,  $q_I$ , and the expected production rate,  $q_p$ . The parameter  $q_I$  scales the time axis and, along with  $V_p$ , is used to convert dimensionless time to real time. A high injection rate would mean a faster flood where the oil is recovered sooner. The model creates this by predicting a higher oil cut over the life of the flood as well as a shorter flood life. The  $q_p$  parameter is influential in the economics because it controls the total volume of fluids recovered. The recovered fluids must be treated and therefore have costs associated with them.

### **3.8 Summary of the Simplified Enhanced Oil Recovery Method**

The simplified enhanced oil recovery method is based on fractional flow theory and Koval's method. It is designed to characterize an oil production history curve with a few simple parameters that are used to generically represent the effects of a larger number of parameters.

The method allows for quick easy simulations that create accurately representative production history curves, which creates significant advantages over conventional models for predicting the recovery of oil. These attributes are important to a decision analysis that is designed to account for a wide range of possible outcome and uses probabilities determine the expected value of a project.

## **CHAPTER 4: EVALUATION OF THE SIMPLIFIED ENHANCED OIL RECOVERY METHOD**

### **4.1 Introduction**

The simplified enhanced oil recovery method (SEORM) is based on theory about the flow of oil and displacing fluids, as discussed in Chapter 3. The method must be evaluated with field data in order to develop confidence in the method's forecasting abilities. SEORM is evaluated using data for surfactant-polymer (SP), alkali-surfactant-polymer (ASP), and CO<sub>2</sub> floods.

The method hinges heavily on the input of several technical variables, including:  $K_1$ ,  $K_2$  (or  $K_f$ ),  $v_{oB}$ ,  $S_{oF}$  (or  $\Delta S_o$ ), and WAG (for CO<sub>2</sub> floods). Each parameter accounts for several characteristics associated with enhanced oil recovery (EOR) projects. For example, the Koval factors,  $K_1$  and  $K_2$ , help describe the shape or behavior of the oil recovery through the life of the flood. These factors account for the influence of the reservoir's heterogeneity, the mobility of the fluids in the reservoir, the affects of salinity, clay content, adsorption of chemical agents, and other influencing properties of the flood or reservoir. Therefore, the Koval factors by themselves cannot be calculated easily or predicted based on data existing before EOR flooding. Through the evaluation of SEORM, the technical inputs were calibrated based on the EOR flood type so that at least ranges could be determined. From these ranges, various potential scenarios of oil recovery can be simulated. The objective of this chapter is to discuss how the evaluation

is performed and to discuss ranges of values for certain parameters as well as any conclusions about the method and the fits.

## **4.2 General Discussion of the Data Used for Validation**

The evaluation of SEORM is based on 30 field and pilot scale projects. Of the 30, 19 are SP floods, three are ASP floods, and eight are CO<sub>2</sub> floods. The information for the fields comes from papers published in journals and conferences. Therefore, much of the data used for the evaluation comes from sources that have already summarized and reduced the data from field performances. There was difficulty in finding complete data necessary for project evaluation for ASP and CO<sub>2</sub> floods; hence, there are fewer field validations.

The majority of the SP floods occurred between the 1960s and 1990s, while most of the ASP and CO<sub>2</sub> floods occurred after 1990.

The majority of the fields studied are from the US. Only a couple of international projects are included in the evaluation, due to the general lack of necessary information for many international projects in the literature.

## **4.3 The Evaluation Process**

A typical method is used for fitting SEORM against field data. To illustrate the process, an example fitting is discussed with data from the Bell Creek field.

### **4.3.1 Necessary Field Data**

All of the data used for the fitting came from Hartshorne and Nikonchik's (1984) paper. The paper provided a comprehensive review of the field's history, properties, and

performance of the SP flooding. Table 4-1 is a summary of the inputs provided the paper.

**Table 4-1 Summary Inputs Determined from Hartshorne and Nikonchik (1984)**

**Field Layout**

Size	179	acres
Spacing	20	acres
Pattern	Five spot	
Number of Injectors	9	
Number of Producers	16	

**Reservoir Properties**

$S_{ol}$	0.800	
$S_{oR}$	0.330	
$B_o$	1.026	RB/STB
Pore volume	8.600E+06	RB
Oil Viscosity	6	cp
Brine Viscosity	1.2	cp
$f_{ol}$	0.029	

**Performance/Design Properties**

Injected Fluid	Water	Polymer	Surfactant	Units
Injection Rate	7300	7300	2800	STB/day
Production Rate	17800	17800	8900	STB/day
Slug size (injected)	--	0.93	0.046	Frac. $V_p$

There are various injection and production rates used in the fitting because the rates varied considerably over the life of the flood. It is common for there to be multiple injection rate for SP floods because each part of the chemical slug is injected at a different rate due to the infectivity of the fluids. The model used with SEORM can handle three different rates, one for each part of the flood: surfactant injection, polymer injection, and chase water injection. In the future, the model could be adapted to handle more volatile rates.

The data provided in Nikonchik's paper did not include much information about properties for fractional flow curves. Therefore, the descriptive values come from Vargo's (1978) paper.

The most critical piece of information for the fit is the history of the flood. Figure 4-1 is a plot of the provided oil production history. The data is digitized and put into Microsoft EXCEL and then matched with SEORM.

Fig. 13—Comparison of TIP patternflood production and chemically mobilized oil production.

Figure 4-1 Plot of the Provided Flood Performance of the Field for Bell Creek from Hartshorne and Nikonchik (1984)

The data from Figure 4-1 is then converted into dimensionless time of injected pore volumes,  $t_D$ . The following equation is used for the conversion

$$t_D(t) = \frac{qt}{V_p}$$

**Equation 4-1**

where  $t$  is time,  $q$  is the injection rate, and  $V_p$  is the total pore volumes of the reservoir. The data is plotted in terms of oil saturation and oil cut against dimensionless time for the fitting. Figure 4-2 is a plot with the digitized data.

### **4.3.2 The Fitting Process for Surfactant-Polymer and Alkali-Surfactant-Polymer Floods**

The following process is applied to surfactant-polymer (SP) and alkali-surfactant-polymer (ASP) floods.

The fits used for the evaluation are based on the oil cut against dimensionless time curves. The oil cut curves are used because they represent the history of oil production, which is important to economics. Furthermore, by using both oil cut and dimensionless time, two dimensionless variables, the fits could be compared to one another between different field results, regardless of scale.

The fits are based on a coefficient of determination,  $R^2$ , as defined by the following

$$R^2 = 1 - \frac{\text{Average squared difference}}{\text{Variance}} = 1 - \frac{\frac{\sum (f_o^{\text{data}} - f_o^{\text{model}})^2}{n}}{\frac{\sum (f_o^{\text{data}})^2}{n} - \frac{(\sum f_o^{\text{data}})^2}{n^2}}$$

**Equation 4-2**

where  $f_o^{\text{model}}$  is the average oil cut from SEORM,  $f_o^{\text{data}}$  is the average oil cut from the data, and  $n$  is the number data points (Ang and Tang 2007).  $R^2$  values close to one

signify strong fits with one being a perfect fit. Negative valued fits are possible because the model does not create perfectly linear curves to represent no fit.

To create the fits, the parameters  $S_{oF}$ ,  $K_1$ ,  $K_2$ , and  $v_{oB}$  are adjusted until a seemingly a good fit is attained.  $S_{oF}$  is the assumed final oil saturation attainable for the EOR flood,  $K_1$  and  $K_2$  are Koval factors, and  $v_{oB}$  is the specific shock velocity of the oil bank. Most of the fits for SP and ASP floods could be improved by altering  $V_p$  by either increasing or decreasing the value; however, the  $V_p$  provided is never altered for the SP or ASP flood data because it considerably opens up the flexibility of the fits. Altering  $V_p$  means that the dimensionless time and the volume of recoverable oil is changed. These changes allow for different Koval factors,  $S_{oF}$ , and  $v_{oB}$  values to fit with different  $V_p$ . Therefore, allowing  $V_p$  to be adjustable leads to a wide range of potential fits.

Initially trial and error and “eye-balling” are used to create fits. The excel program, Solver, is then used to perform a maximization of the fit. Trial and error is necessary to determine a starting point for maximizing the fit because Solver is unable to find a good fit from arbitrary starting points.

The results produced by Solver are reviewed and adjusted if they seem irregular. For example, corrections are made if it would be impossible to fit a fractional curve to the provided results. Overall, corrections are rare. Table 4-2 summarizes the fitted parameters for Bell Creek. Figure 4-2 through Figure 4-4 are plots of SEORM with the data. The fit are strong against the provided data. For the Bell Creek case, the full life of the flood is not provided and therefore a significant portion is extrapolated.

**Table 4-2 Summary of Fitted Parameters for Bell Creek Field**

Fitted Parameters	
$S_{oF}$	0.198
$\Delta S_o$	0.13
$K_1$	1.25
$K_2$	2.00
$V_{oB}$	2.00

**Figure 4-2 Plot of Oil Cut against Dimensionless Time for the Bell Creek Field**

Figure 4-3 Plot of Oil Saturation against Dimensionless Time for the Bell Creek Field

Figure 4-4 Plot of Oil Production Rate against Time for the Bell Creek Field

In Figure 4-4 there appears to be a jump in oil rate at about 100 days. This jump is because of an instantaneous jump in injection rate as well as production rate. If the spreadsheet is designed to better handle varying rates, then a smoother transition could be modeled. In Appendix A several plots have a jump appear in either in the oil production or oil cut plot because of the jumps in rates.

#### **4.3.3 Fitting the Fractional Flow Curve**

The fractional flow curves are also fitted to ensure that the theory behind the fit was maintained. Parameters of  $S_{oF}$  and  $v_{oB}$  are the most critical for the curve. The values for parameters  $S_{oF}$  and  $v_{oB}$  are based on the best fits to the field history data. The critical points for the curve are the initial and the final points for the flood. The initial point for the EOR flood is defined by the oil cut,  $f_{oI}$ , and the oil saturation,  $S_{oR}$ , at the time the EOR flood is initiated. It is assumed that the values provided in the paper are accurate and therefore a point on the curve is known. Another important point is the starting point of the water-oil curve,  $S_{oI}$  or  $S_{wI}$ , which in the case of Bell Creek is provided. Assuming that the fit matches the theory, then the intersection of the lines for  $v_{oB}$  and  $v_C$  is a second point on the curve. The parameter  $v_C$  is specific shock velocity of the injected fluids. The parameter  $v_C$  is defined by  $S_{oF}$  for SP and ASP floods. The provided viscosities for the water and oil in the reservoir give some information on the shape of the curve. The remaining parameters for the field came from another paper about the Bell Creek field. Vargo's 1978 paper provided information on the fractional flow curve for the field.

Data from Vargo's paper is used to help define the end point relative permeability of water ( $k_{rw}^o$ ), end point relative permeability of oil ( $k_{ro}^o$ ), Corey type exponent for water (n), Corey type exponent for oil (m), and residual oil saturation ( $S_{or}$ ). The parameters  $k_{rw}^o$ ,  $k_{ro}^o$ , n, and m control the shape of the curve, while  $S_{or}$  controls an end point of the curve. Table 4-3 is a summary of the fitted parameters and Figure 4-5 is a plot of the curve.

For most fields, data about the fractional flow curve for the field is not provided and therefore values for the defining parameters are fitted. Based on the best fitting  $v_{oB}$ ,  $S_{oF}$ , and the initial condition at the start of the flood, there are two points that could be used to fit a curve. The one point is the initial condition of the flood and the other is the intersection of the  $v_{oB}$  and  $v_C$  lines. Typically the viscosity of the oil is provided, but the viscosity of the brine is assumed to be one cp. The values for, n, m,  $k_{rw}^o$ ,  $k_{ro}^o$ ,  $S_{oI}$ , and  $S_{or}$  are altered till the curve passes through the two points. Table 4-4 is summary of typical starting values. For equations of how the fractional flow curve is constructed, refer to section 3.5.3.

**Table 4-3 Summary of Fitted Parameters for the Fractional Flow Curve for Bell Creek Field from Vargo (1978) and Hartshorne and Nikonchik (1984)**

Fitted Parameter	
$k_{rw}^o$	0.18
$k_{ro}^o$	0.80
n	1.75
m	2

#### 4.3.4 The Fitting Process for CO<sub>2</sub> Floods

There fitting process is a bit different for CO<sub>2</sub> floods from the process used for SP and ASP floods because of the importance of the design parameter of water to solvent (WAG) ratio.

The methodology for the fittings is the same as with SP and ASP. The key difference in the process is which parameters were used for fitting. The parameters  $S_{oF}$ ,  $K_1$ ,  $v_{oB}$ , WAG, and  $V_P$  are adjusted until a strong fit based on  $R^2$  is established. Instead of using  $K_2$  as a fitting parameter,  $K_{2,max}$  is used because it is assumed that the solvent and the oil bank arrive at the producer at the same time. For CO<sub>2</sub> floods it is very typical for the solvent to arrive before the oil shock; however, the model is unable to handle that condition and the best approximation was to assume the oil and solvent banks breakthrough at the same time.

The total pore volume,  $V_P$ , is also a fitting parameter for CO<sub>2</sub> floods because the estimated  $V_P$  provided in the literature is typically very high and fits are not possible. The WAG ratio values provided in the literature are used for the fits. The model cannot handle WAG ratios of zero and therefore a minimum value is set at one. If substantial fractional flow curve data is also provided then  $v_{oB}$  is essentially provided and not altered much for the fits. Therefore, only  $S_{oF}$ ,  $K_1$ , and  $V_P$  are altered for most cases. For cases where there is not much fractional flow data or the WAG ratio is zero or unknown then the fits include more parameters.

There is not as much of an issue with  $V_p$  being a fitting parameter for CO<sub>2</sub> floods as there is for SP and ASP floods because  $K_2$  is set at  $K_{2,max}$  and the WAG ratio is typically another piece of information for the field. The extra information helps to limit the potential number of satisfactory fits. The decision analysis considers a varying  $V_p$  because of SEORM's sensitivity to the parameter and the belief that the originally predicted  $V_p$  could be inaccurate.

#### 4.4 Summary of the Fits for All of the Flood Types

SEORM is able to fit every field relatively closely. Table 4-5 through Table 4-7 are summaries of the fits for the two flood types. Appendix A includes the fitted plots and fitting parameters for each field. The fits are constructed so that the provided data from the literature and SEORM matched as closely as possible.

In Table 4-5 through Table 4-7,  $\Delta S_o$  is the change in average saturation and is defined as

$$\Delta S_o = S_{oR} - S_{oF}$$

**Equation 4-3**

“Rec. Eff.” Stands for recovery efficiency and is defined as

$$\text{Rec. Eff.} = \frac{\Delta S_o}{S_{oI}}$$

**Equation 4-4**

The parameter  $K_f$  is a factor term that scales  $K_2$  so that it falls between  $K_1$  and  $K_{2,max}$ .  $K_{2,max}$  is the upper bound limit for  $K_2$  values and it is defined as

$$K_{2,\max} = \frac{K_1 V_{oB}}{V_C}$$

**Equation 4-5**

$K_f$  is defined as

$$K_f = \frac{K_2 - K_1}{K_{2,\max} - K_1}$$

**Equation 4-6**

All of the fits are relatively strong with having an  $R^2$  value of over 0.7. The only glaring exception is the Manvel pilot. The fit appears weak because the project was unsuccessful and it did not experience a notable increase in oil cut, as shown in Figure 4-6. Therefore, SEORM is unable to create a satisfying fit to the data. However, the best fitting values did produce a curve that demonstrated poor performance.

**Figure 4-6 Plot of the Manvel Data with the SEORM Fit for the Oil Cut Curve**

## 4.5 Analysis of the Fits

To create a better understanding about the results of the fits, some basic statistical information is calculated for each flood type. Included in the analysis is the range of values, the mean value, standard deviation, and coefficient of variation for each parameter as shown in Table 4-9. The SP floods are also divided between field and pilot scale. The ASP flood data is not analyzed in this manner because there is not enough data sets yield anything insightful. One must be careful when looking at these comparisons because there only a few sets of data for each scale and flood type. A larger sample space would yield more confidence for the comparison. Along with the table, box plots are made to help visualize the distribution of values.

**Table 4-9 Summary of Statistical Information for the Fitted Parameters for SP and CO<sub>2</sub> Flood Data**

#### 4.5.1 Comparison of Scale for SP Floods

A review of Table 4-9 leads to several important observations about the difference between scale and flood type. There appears to be a distinction between the field and pilot scale projects. The field scale projects for the SP floods seem to have similar  $S_{oR}$ , which was expected because EOR is typically considered at the end of water flooding, but higher  $S_{oF}$  and lower  $\Delta S_o$  than the pilot projects. This result is expected since good contact between chemical and oil is less likely with larger scale projects because the chemical agents are more likely to degrade, be adsorbed, or leak out the expected reservoir leading to a lower volume of mobilized oil.

Figure 4-7 is a comparison of the distribution of  $\Delta S_o$  based on project scale. The pilot cases seem to have a wider distribution that is more oriented towards higher values than the field cases. This suggests that when studying smaller reservoir increments, one may observe higher variability in  $\Delta S_o$ . Data from Chateaufrenard is considered to be an outlier because the results from that project are significantly different when compared to other projects. The change in oil saturation for the project is almost three times higher

than the next highest value. This likely suggests that the either the assumed total pore volumes for the project is low or that the oil saturation at the start of tertiary is low.

**Figure 4-7 Distribution of  $\Delta S_o$  for Pilot and Field Scale SP Floods**

Figure 4-8 is a plot of the distribution for the values of  $K_1$  and  $K_2$  for both pilot and field cases for the SP flood data. The distribution of both Koval factors is wider for the field cases with a tendency to be skewed towards higher values. Also, the distribution of  $K_1$  for both field and pilot projects are skewed towards higher values while  $K_2$  appears to have a more symmetrical distribution. The average value for  $K_1$  does not vary significantly between field and pilot scale projects. However, the distribution for  $K_1$  seems to have a greater skew towards larger values for field projects. This is again likely for the same reasons as for  $K_2$ .

**Figure 4-8 Distribution of Koval Factors for Pilot and Field Scale SP Floods**

Figure 4-9 is a plot of the distribution of  $K_f$  for field and pilot projects. It is surprising to see that the distribution for  $K_f$  is narrower for the field scale projects than for the pilot scale. However, the field distribution is more restricted to the higher region with a slight skew to the left.

**Figure 4-9 Distribution of  $K_f$  for Pilot and Field Scale SP Floods**

The field projects are better fitted with higher  $K_2$  and  $K_f$  values than the pilot projects. This implies that field scale projects are more likely to behave more heterogeneously. Again, this is expected as larger scale projects are expected to have

more heterogeneity in the medium and mobility would be more likely to be less favorable because of polymer deterioration and adsorption.

In regards to the parameter  $v_{oB}$ , the field scale projects tend to have larger values. This may suggest that channeling is a more significant issue at the field scale than pilot scale. At larger scales, there tends to be more heterogeneity meaning that there is a higher likelihood that channeling would occur; therefore, this result makes sense. Figure 4-10 is a plot of the distributions for  $v_{oB}$ . The distribution for the field projects tends to have a slightly larger median; yet the two distributions do compare somewhat closely.

Data from the Big Muddy field and pilot scale projects are marked as outliers because they are significantly higher than the rest of the data. The next highest  $v_{oB}$  value for both the field and pilot data is 4.5. It is peculiar that both the pilot and field data produced similar high  $v_{oB}$  results, suggesting that the high  $v_{oB}$  is because of field properties. It could also be a direct result of an inaccurately reported total pore volume.

**Figure 4-10 Distribution of  $v_{oB}$  for Pilot and Field Scale SP Floods**

ASP and SP floods should behave similarly because the two flood types have similar mechanisms for oil recovery. The ASP data is not added to the SP data because it would skew the data regarding saturations. The ASP floods reviewed injected the

chemicals relatively early in the field's life when compared to SP floods. Therefore, they have higher  $S_{oR}$  and  $\Delta S_o$  values. The values for  $S_{oF}$ ,  $K_1$ ,  $K_2$ ,  $K_f$ , and  $v_{oB}$  are not out of reason when looking at the summary for SP data; however, more data is required before any conclusions can be made.

#### 4.5.2 Comparison of Flood Types; SP and CO<sub>2</sub>

There are differences between flood types between the SP and CO<sub>2</sub> data for all of the fitting parameters. Figure 4-11 is a plot of the distributions comparing The CO<sub>2</sub> floods appear to have larger  $S_{oF}$  values than SP, which is consistent with theory because CO<sub>2</sub> floods do not mobilize as much residual oil as surfactants.

Figure 4-11 Distribution of  $S_{oF}$  for SP and CO<sub>2</sub> Floods

Figure 4-12 is a comparison of the distribution of  $\Delta S_o$  between SP and CO<sub>2</sub> floods. Despite the higher  $S_{oF}$ , CO<sub>2</sub> floods have  $\Delta S_o$  values that are larger than for SP floods, because CO<sub>2</sub> floods typically start at higher oil saturations and a slightly earlier in the life of the field than SP floods. The CO<sub>2</sub> data is compared to the SP field data because most of the CO<sub>2</sub> data is from field scale projects. The CO<sub>2</sub> floods distribution is larger and is more oriented towards the larger values. The higher  $\Delta S_o$  values and large

distribution may be a direct result of allowing  $V_P$  to be a fitting parameter for the  $\text{CO}_2$  fittings. Smaller  $V_P$  values than estimated may suggest lower  $S_{oF}$  and higher  $\Delta S_o$  values for the flood because if the recovered volume of oil does not change. Therefore, if  $V_P$  decreases then  $\Delta S_o$  must increase to maintain mass balance. If the fits for the SP flood are redone with a varying  $V_P$ , then the distribution and value for  $\Delta S_o$  could potentially increase.

**Figure 4-12 Distribution of  $\Delta S_o$  for SP and  $\text{CO}_2$  Floods**

Figure 4-13 compares the distributions for  $v_{oB}$  for  $\text{CO}_2$  and SP floods. The  $v_{oB}$  values are considerably larger for  $\text{CO}_2$  floods. The distribution for the  $\text{CO}_2$  is larger and it is situated at higher values than the SP flood distribution. It does appear that the  $v_{oB}$  values are generally higher than SP, especially if the Big Muddy outlier is to be neglected. This is likely a result of the miscibility of  $\text{CO}_2$  gas with the oil as direct result of pressure variation that occurs between layers within the reservoir during the flood. The large mobility ratio that is typical for  $\text{CO}_2$  also leads to channeling and larger  $v_{oB}$  values.

**Figure 4-13 Distribution of  $v_{oB}$  for SP and CO<sub>2</sub> Floods**

Figure 4-14 is a comparison of the Koval factors for SP and CO<sub>2</sub> floods. The average values of both Koval factors are higher for CO<sub>2</sub> floods than for SP floods. The distributions are also larger for CO<sub>2</sub> floods. These distributions suggest that CO<sub>2</sub> floods are more likely to experience heterogeneous behavior and therefore have a longer recovery period than SP floods. This result is consistent with historical performances of CO<sub>2</sub> floods. The heterogeneous behavior is most likely a result of the relatively poor mobility of the solvent water mix and the oil.

**Figure 4-14 Distribution of Koval Factors for SP and CO<sub>2</sub> Floods**

Although the above discussion calls out certain effects for the cause of certain trends, a review of the data does not actually find any strong correlations between any reservoir characteristic parameters and either the Koval factors,  $\Delta S_o$ ,  $S_{oF}$ , or  $v_{oB}$ . This is likely because so many different factors contribute to how a flood behaves and each parameter essentially captures how all of the factors work together, rather than singling out one or two. Attempts at determining linear relationships between different reservoir characteristics and fitting parameters can be found in Appendix B.

#### **4.5.3 Discussion of the Outliers and Fitting Issues**

All of the data sets are fitted relatively well by SEORM. It is, however, observed that some fits are questionable. Some projects appear to be outliers. As an example the Big Muddy data is best fitted with large  $v_{oB}$  values that are considerably larger than those used for other SP floods. One possible explanation for this is that the reported  $V_p$  is inaccurate. Inaccuracy with the reported  $V_p$  could be common because it is an estimate based on an assumed porosity and net pay thickness. It is also unknown if the injected chemicals will ever be able to sweep the entire reservoir as well. In the case of Big Muddy, if a lower  $V_p$  is assumed, then the fit can be improved considerably. New values can be found that fit both the Big Muddy field and pilot data reasonably well.

**Figure 4-15 Plot Comparing Fits for the Big Muddy Field with Altered  $V_p$**

Another standout outlier is the data from the Chateaugay pilot. The pilot appeared to perform exceptionally well with almost perfect recovery predicted. Such high recovery is unlikely and assuming that the oil production data is accurate, then there is likely an error with the total pore volumes. Chances are that the reservoir may actually be larger than estimated.

Other sources of error with the fits include problems with handling the varying injection rates and inaccuracies with the assumed  $S_{OR}$ . As mentioned earlier, SEORM is able to handle up to three different injection and production rates; however, most of the data sets have varying rates for various reasons. Assuming up to three values works well for most of the fields.

Errors involving  $S_{OR}$  are likely because of the difficulty associated with measuring an accurate value that is representative of the entire project. An error with  $S_{OR}$  is not significant in regards to the actual fit with SEORM, but it does create issues for the fitting

with the fractional flow curve because it influences the location of the start of flood point, a point the curve must pass through.

## 4.6 Comparison of Fittings for Similar Projects

There are several sets of data from the same oil reservoir. Some of these projects are pilot and field scale projects and others are of the same scale. It is important to see if SEORM produces consistent results between projects from the same reservoir, assuming similar injection techniques and chemicals are used.

### 4.6.1 Comparison of Pilot and Field Scale Projects

There are three reservoirs with pilot and field scale data used in the evaluation, Berryhill, Big Muddy, and Robinson (M-1). The results of their fits are summarized in Table 4-10. There appears to be a decent correlation between pilot and field results. The data and fit for Berryhill is used as example to explain how pilot and field scale projects from the same reservoir are treated, the following discusses the Berryhill project.

**Table 4-10 Summary of Fitted Values for Pilot and Field Scale Projects: Big Muddy, Robinson, and Berryhill**

Parameter	Big Muddy (Original)		Robinson/M-1			Berryhill	
	Pilot	Field	Pilot	Field	Field	Pilot	Field
WS (acres)	1	10	0.8	2.5	5	4.5	20
$V_p$ (RB)	1.40E+05	8.60E+06	2.70E+04	9.00E+06	9.00E+06	7.24E+05	1.20E+07
$S_{oF}$	0.22	0.23	0.27	0.31	0.32	0.22	0.22

$K_2$	2.17	4.10	2.20	2.42	2.4	3.90	7.36
$K_f$	0.14	0.30	0.44	0.43	0.43	2.10	2.50
$v_{oB}$	8.05	8.70	2.80	3.10	3.2	0.88	1.00

The Berryhill field, also known as Glenn Pool field, is in Creek County, Oklahoma. The chemical EOR project began in the late 1970s with a pilot that was later expanded to a field project in the early 1980s. Data for the pilot and field came from three papers: Crawford and Crawford 1985; Bae and Syed 1988; Bae 1995. Figure 4-16 is a figure of the fits for the pilot and field data.

Table 4-11 is a summary of the parameters that describe the characteristics of the reservoir that should be the same for the two projects. Shaded values are those that are assumed and not provided by the papers. The assumed values are altered until they best fit both the pilot and field data. Table 4-12 is a summary of parameters unique to each project. Again the shaded values are fitted.

**Figure 4-16 Fits of the Berryhill Pilot (Left) and Field (Right) with SEORM**

**Table 4-11 Summary of Common Parameters for Berryhill Pilot and Field Projects**

$B_o$	1	RB/STB
$\mu_o$	4	cp
$\mu_w$	1	cp
$f_{ol}$	0.010	
$k_{rw}^o$	0.175	
$k_{ro}^o$	0.8	
$n$	3	
$m$	2	

**Table 4-12 Summary of Fitted Parameters for Berryhill Pilot and Field Projects**

Fitted Parameters	Pilot	Field	Units
Size	18	160	acres
Spacing	4.5	20	acres
Injection Scheme	5-spot	5-spot	
$V_p$	7.24E+05	1.20E+07	RB
$S_{oF}$	0.220	0.215	
$\Delta S_o$	0.083	0.088	
$K_1$	2.50	3.75	
$K_2$	3.90	7.36	
$v_{oB}$	2.10	2.50	
$K_f$	0.88	1.00	

Various conclusions can be drawn from comparing the results of the fits for the two scales. The first is that both scales had a similar  $\Delta S_o$  value which is a critical parameter regarding a project's potential for profitability because it describes how much volume of oil could be recovered.

Another observation is the well spacing for the two scales. As is common practice, the pilot has a smaller well spacing than the field; however, the overall recovery does not appear to have been adversely affected. Rather the behavior of the flood seems to strongly reflect the effects of the well spacing. The pilot is fitted with lower Koval factors,  $K_f$ , and  $v_{oB}$  values than the field, as is expected.

The magnitude of the increase in the values for the Koval factors is a bit surprising, in particular  $K_1$ . Even though the pilot under predicted the field's  $K_1$  value, the higher than average value and the tendency for field scale projects to have higher Koval factors suggest to one to use a relatively high  $K_1$  for predicting field scale behavior. Based on the pilot data, a reasonable prediction for the field would be a  $K_1$  of about 3.0 to 3.25.

Observations from the summary in Table 4-10 include that the conclusions made for Berryhill seem to apply to the Big Muddy and Robinson/M-1 cases. Overall the Koval factors and  $K_f$  values increased,  $\Delta S_o$  decreased, and  $v_{oB}$  remained constant when going between the two scales. It is also observed that an extreme, such as the high  $v_{oB}$  value for Big Muddy, is consistent between the two scales. This seems to reaffirm the idea that fitted pilot data could be used to predict field performance.

#### **4.6.2 Comparison of Same Scale Projects**

There is some data for a few large scale projects from the same field, including the M-1 project (part of the Robinson Field), the SACROC project, and the Bradford project. For each field set, the fractional flow curves are the same Table 4-13 is a

summary of the fits for these projects. Of these three projects, the M-1 and SACROC projects demonstrate consistency between its two sets of data.

**Table 4-13 Summary of Fitted Values for Projects from the Same Field**

<b>Field Name</b>	<b>M1-2.5</b>	<b>M1-5.0</b>	<b>Bradford 7</b>	<b>Bradford 8</b>	<b>SACROC 4</b>	<b>SACROC 17</b>
Size (acres)	200	200	46.2	220	600	2700
Well Spacing (acres)	2.5	5	2.89	4.00	40	40
$S_{oF}$	0.31	0.32	0.28	0.34	0.29	0.33
$\Delta S_o$	0.09	0.08	0.13	0.06	0.17	0.13
$K_1$	1.62	1.60	1.59	1.50	2.30	3.00
$K_2$	2.42	2.40	5.00	2.25	6.35	7.90
$K_f$	0.43	0.43	0.95	0.77	1.00	1.00
$v_{oB}$	3.10	3.20	4.50	2.50	3.75	3.20

The fits for the Bradford projects are not close and do not show consistency to the trends discussed in the earlier sections. For example, with the Bradford field it appears that a larger project size and well spacing leads to a more uniform recovery with less channeling, but also a lower  $\Delta S_o$ . There could be various reasons for the discrepancy including a different polymer injection schedule, surfactant slug size, and surfactant concentration.

In the SACROC case, the Koval factors and  $S_{oF}$  and  $\Delta S_o$  follow the trends associated with larger field size. The  $v_{oB}$  does not follow the trend but the values are similar between the two projects. Furthermore, this project has the most complete data for the fractional flow and the fitted parameters also fit the curves, see Appendix A.

## 4.7 Conclusions

SEORM fit well to all of the data sampled and ranges now exist for key SEORM parameters. These ranges provide good starting points when studying fields as potential

EOR candidates. Table 4-14 is a summary of the ranges and average values recommended for a decision analysis for a field scale project. The ranges are based on eight sets of data for SP floods and eight sets for CO<sub>2</sub> fields, and ASP is assumed to behave similarly as SP fields. It is assumed that the field is approaching the end of its economic life and has a low oil cut. If the field is younger, the oil saturation at the start of the flood would be high, then  $\Delta S_o$  should be adjusted to reflect the difference. The ranges are empirical and user judgment is needed when determining the most appropriate values to be used for a decision analysis or EOR forecasting.

**Table 4-14 Recommended Ranges for SEORM Input Parameters**

Parameter	ASP and SP Flood			CO <sub>2</sub> Flood		
	Low	High	Average	Low	High	Average
$\Delta S_o$	0.06	0.16	0.10	0.06	0.14	0.10
$K_1$	1.25	3.5	1.6	1.5	2.5	2.0
$K_2$	2.0	5.0	3.0	2.0	6.0	3.5
$K_f$	0.4	1.0	0.75	0.0	1.0	0.5
$v_{oB}$	2.0	4.0	3.0	3.0	7.0	4.0

The evaluation also demonstrated that values fitted to pilot scale projects do provide some insight as to what to expect for a field scale project and therefore can provide useful information for a decision analysis. For example, if pilot data does exist then there could be more confidence in the appropriate input parameters for SEORM.

Certain trends regarding the fits are also noted. Larger scale projects tend to have higher Koval factors, higher  $v_{oB}$  values, and lower  $\Delta S_o$  values. CO<sub>2</sub> floods tend to have higher Koval factors,  $v_{oB}$  values, and  $\Delta S_o$  values than SP floods. The trends seem to agree with expectations based on the history for each flood type.

## **CHAPTER 5: DEVELOPMENT OF AN ECONOMIC MODEL**

### **5.1 Introduction**

Economics are commonly the attribute used to value a project and to make decisions. The simplified enhanced oil recovery method (SEORM) predicts possible technical outcomes for an enhanced oil recovery (EOR) flood: including the volumes of oil and water produced versus time. The objective of this chapter is to develop a model that quantifies the economic value of each possible technical outcome. The model is intended to account for how the scale, duration, and timing of various expenses influence the value of the project.

#### **5.1.1.1 Economic Criteria**

The economic model adopted herein is based on the cumulative discounted cash flow method (CDCFM) to characterize the economic value. From the CDCFM, one finds the net present value (NPV) of the project at various times, which is the difference between the initial investment and the sum of the total discounted cash flows. The cash flows include all costs and earnings throughout the life of the project. CDCFM uses a discount rate to describe the present day worth of a cash flow. The discount rate reflects the opportunity cost is expected on an investment made today and it represents the rate of return that could be realized with an investment with similar risk (Bosch, Montllor-Serrats and Tarrazon 2007). If the NPV is positive, then the project is profitable. A typical discount rate for an oil production project ranges between five and 15% per year.

There is uncertainty in what the actual discount rate will be; however, assuming zero for this rate is not considered appropriate because any dollar invested in the project could be invested in another project with some kind of expected rate of return greater than zero. The discount rate,  $d$ , is applied as follows

$$PV = \frac{FV}{(1 + d)^t}$$

**Equation 5-1**

where PV is the present value, FV is the future value, and  $t$  is time (Bosch et al. 2007).

The advantage to implementing NPV is that it provides an easy way to directly compare different economic outcomes for projects of comparable scale. Furthermore the method also incorporates the effect of time on the attractiveness of an option, where a longer period of waiting on a financial return reduces its value.

## **5.2 Economic Parameters**

The literature on reports of several field and pilot scale projects of EOR was reviewed to develop an economic model that represented the state of practice reasonably well.

### **5.2.1 Generic Factors**

The following sections address the factors that can be generically applied to each EOR method, including price of oil, taxes and royalties, start-up costs, maintenance costs, injection costs, treatment costs, and inflation.

### **5.2.1.1 Oil Price**

The price of oil is arguably the most critical economic factor, as it strongly influences the profitability of a project. For example, chemical-based EOR projects are generally not economical options unless the oil price is relatively high because the chemicals are expensive. Projects such as the Bell Creek, M-1, and the Berryhill floods were considered to be technically successful projects because additional oil was mobilized and recovered. However they were not economically profitable (Hartshorne and Nikonchik 1984; Stover 1988; and Bae 1995).

Oil price is volatile. According to recent records from the US Department of Energy, the price of oil has fluctuated from \$50/STB in February 2007 to a peak at \$145/STB in July 2008, and then dropped to \$40/STB in December 2008. This is a variation in price of about \$100 over a period of a year and half. A large-scale EOR project is expected to last over a decade and is likely to experience several wide fluctuations in oil price.

Predicting oil price for the life of a flood with certainty is impossible. Many have tried to create models to forecast price, with some of the most comprehensive ones implementing thousands of inputs. Such inputs include global politics, energy consumption, technological trends, country development, and predicted production rates. Though no model can claim to be accurate over the span of decades, they do seem to imply that the general trend is for the price to be on the rise as more developing countries increase their energy demands (Belhaj and Lay 2008).

### 5.2.1.2 Taxes and Royalties

Several types of taxes typically apply to oil recovery projects: ad-valorem tax, severance tax, income tax, and royalties (White, Gorrington and Odeh 1986). An income tax is a tax applied to the profits made by an individual or company (Forbes 2010). For the economic model it was neglected because the tax is applied to a company as whole, which makes it difficult to determine how much an individual project would be taxed. The ad-valorem tax is a tax that is applied to the value of the land of any real-estate. It can vary from state to state, but is typically between two percent of five percent of the total value of a company's assets. The severance tax is a tax that is applied to the removal of non-renewable resources. Some wells may be exempt from severance tax based on their production rate. Royalties refers to money owed to owner of the property from which oil is recovered. This fee is applied to the earnings from the sold recovered oil. Typically royalties are either 12.5% or 16.7% (American Petroleum Institute 2009). The ad-valorem tax is applied to property that is owned by the oil company and the royalty is applied to oil recovered from property owned by others. Table 5-1 is a summary of typical rates.

**Table 5-1 Typical Values for Taxes and Royalties**

<b>Tax</b>	<b>Rate (%)</b>
Ad-valorem	5.0
Severance	5.0
Royalty	12.5

These rates do vary somewhat from field to field, though they should be well understood when evaluating a field and therefore are not uncertain. Some projects have the potential to qualify for a tax credit for using EOR methods.

#### **5.2.1.3 Injection, Treatment, and Disposal Costs**

The injection cost, applied per barrel of injected fluid, accounts for all steps and measures necessary for the preparation and injection of fluids. The cost is applied both during the injection of the chemical slugs and the chasing water.

The treatment cost is applied per barrel of oil recovered. It is supposed to account for extra expenses involved with separating the chemicals from the oil. The water disposal cost captures the expenses for treating recovered water before disposal or reinjection (White, Gorrington and Odeh 1986). These values may contain some uncertainty. Table 5-2 is a summary of typical values (Anderson et al. 2006).

**Table 5-2 Typical Values for Injection, Treatment, and Disposal Costs**

<b>Cost</b>	<b>Rate (\$/STB)</b>
Fluid Injection	0.10
Oil Treatment	0.10
Water Disposal	0.15

#### **5.2.1.4 Start Up and Maintenance Costs**

At the start of an EOR project, there are several initial expenses that must be considered. These include creating a mixing plant for preparing the injected chemical, building water supply lines, building new wells, converting some wells from producers to injectors, and investigation and engineering expenses. All expenses are typically

proportional to the scale of the project. Of the fore-mentioned upfront expenses, the most significant is the development and preparation of new wells (White, Gorrington and Odeh 1986). Generally, a field being developed for an EOR project will require smaller well spacing to promote better sweep. The only exception may be for CO<sub>2</sub> floods, which can be implemented without the development of new wells.

EOR projects also require maintenance and observation of all of the wells. The maintenance expense accounts for well operation costs, fracturing expenses, engineering expenses over the life of the flood, and maintenance of the wells and other equipment. Typical values are about \$150/day/well (White, Gorrington and Odeh 1986; and Anderson et al. 2006) (White, Gorrington and Odeh 1986; and Anderson et al. 2006).

Both the upfront and maintenance costs are uncertain. Various problems with the geology or shape of the formation can create issues making well spacing and development problematic. Furthermore problems with well operations have been frequently reported and could become an issue for any flood.

#### **5.2.1.5 Inflation**

Inflation is used to account for the potential of a general increase in expenses over time. Inflation does have moderate uncertainty and a typical value is between five and ten percent (White, Gorrington and Odeh 1986).

#### **5.2.2 Factors Unique to Specific Floods**

Each type of isothermal flood has its own unique expenses. These unique expenses primarily deal with the price of the injected chemical.

#### **5.2.2.1 Polymer Expenses**

The cost for polymer captures the costs of the raw material at market price and shipping the material to the site. A typical value for the price of polymer is in the range of about \$1/lb to \$2/lb, and higher oil price often implies higher polymer cost because the polymer is a hydrocarbon product (Wyatt, Pitts and Surkalo 2008). There is uncertainty with the value of the polymer as it may fluctuate over the life of a flood.

#### **5.2.2.2 Surfactant-Polymer Expenses**

Surfactant-polymer (SP) floods include the expenses associated with polymer floods as well as additional ones involving the surfactant. Usually admixtures are injected with a surfactant such as a cosurfactant, cosolvent, and salt. The cost of the surfactant mixture includes shipping of the raw material to the site. The cost of the surfactant can range significantly with a typical range of about \$2/lb to \$3/lb (Wyatt, Pitts and Surkalo 2008). There is considerable uncertainty with this parameter, in particular because the composition of the admixture is uncertain.

#### **5.2.2.3 Alkaline-Surfactant-Polymer Expenses**

Alkaline-surfactant-polymer (ASP) floods involve expenses associated with SP floods as well as additional ones for the alkali agents. ASP floods use either caustic soda (NaOH) or soda ash (Na<sub>2</sub>CO<sub>3</sub>) as the alkaline agents. Typical costs for caustic soda and soda ash are approximately \$0.10/lb to \$0.50/lb (Wyatt, Pitts and Surkalo 2008).

ASP floods are unique in that they may require higher treatment costs than the other floods because the injected brine must be softened to some degree. The softening cost may range between \$0.05/STB to \$1.00/STB (Wyatt, Pitts and Surkalo 2008).

There is considerable uncertainty with the price for injecting the alkali resulting from uncertainty over the identity of the alkali agent and the necessary softening cost.

#### **5.2.2.4 CO<sub>2</sub> Expenses**

CO<sub>2</sub> floods use a gas that it is often mixed with water to mobilize oil. The price of the gas varies considerably based on whether it comes from a natural or industrial source. Currently, the price range is between one and four dollars per thousand standard cubic feet (Mohan 2008). The implemented unit costs account for expenses from transporting the gas to the site. The CO<sub>2</sub> price is proportional to the price of oil because most sources of CO<sub>2</sub> are related fossil fuels (Mohan 2008). The high variability in the cost of CO<sub>2</sub> suggests there is substantial uncertainty.

#### **5.2.3 Summary of Input Parameters**

Table 5-3 summarizes typical values for the economic parameters that affect the value of an EOR project.

**Table 5-3 Summary of Economic Parameters**

<b>Economic Parameter</b>	<b>Variable</b>	<b>Typical Value (2008)</b>	<b>Potential Range</b>	<b>Rate</b>
Price of Oil	$P_O$	70	40 - 120	\$/STB
Escalation Factor	$R_E$	3.0	-2 - 6	%/year
Severance Tax	$T_S$	5.0	4 - 6	%
Ad-Valorem Tax	$T_V$	5.0	4 - 6	%
Royalty	$T_R$	12.5	12.5 - 16.7	%
Inflation	$i$	5.0	3.0 - 8.0	%/year
Discount Rate	$d$	5.0	3.0 - 8.0	%/year
Fluid Injection Cost	$C_q$	0.10	0.05 - 0.20	\$/STB
Oil Treatment Cost	$C_T$	0.10	0.05 - 0.20	\$/ STB
Water Disposal Cost	$C_{WD}$	0.15	0.05 - 0.30	\$/ STB
Start Up Cost	$C_I$	1,500	750 - 3,000	\$/M/well
Maintenance Cost	$C_M$	150	100 - 300	\$/day/well
Polymer Price	$C_P$	1.00	0.70 - 1.50	\$/lbm
Surfactant Price	$C_{Sur}$	2.00	1.50 - 3.00	\$/lbm
Alkali Price	$C_A$	0.30	0.10 - 0.50	\$/lbm
Softening Cost	$C_{Soft}$	0.50	0.00 - 1.00	\$/STB
CO <sub>2</sub> Price	$C_{CO2}$	2.00	1.00 - 4.00	\$/Mcf

### 5.3 Economic Model

The economic model is implemented by marching forward through time in discrete steps of  $\Delta t$ . For each time step, it calculates the discounted present value of the earnings and expenses and then sums all of the steps together to calculate the net present value of the project at a specified time.

#### 5.3.1 Income

The first step is to establish the price of oil at a given time,  $t_j$ , during the flood. For this work, a constant oil price that represents the average price over the life of the flood is used. In addition, the model includes an escalation factor that captures an

annually compounded trend of increasing or decreasing oil price with time over the life of the project. The following defines oil price

$$P_o(t_j) = P_o(1 + R_E)^{t_j}$$

**Equation 5-2**

where  $P_o(t)$  is the price of oil at time  $t_j$ .

The total income or earnings,  $E(\Delta t_j)$ , over a time step,  $\Delta t_j$ , centered about  $t_j$  is

$$E(\Delta t_j) = P_o(t_j)N_P(\Delta t_j)$$

**Equation 5-3**

where  $N_P(\Delta t_j)$  is the cumulative oil produced during  $\Delta t_j$ .

### **5.3.2 Expenses**

From the earnings, the total owed in taxes and royalties in time step  $\Delta t_j$ ,  $T(\Delta t_j)$ , is calculated from

$$T(\Delta t_j) = (T_R + T_S)E(\Delta t_j) + (T_V L)(1 + i)^{t_j}$$

**Equation 5-4**

where  $L$  is the value of the property at the start of the project. In this model, inflation is applied to all cost and expenses. Inflation is applied to the ad-valorem expense because as time passes the value of the land is expected to increase.

To calculate the cost of the injected chemical,  $I(\Delta t_j)$ , over  $\Delta t_j$ , the following is applied

$$I(\Delta t_j) = (m_P(\Delta t_j)C_P + m_{Sur}(\Delta t_j)C_{Sur} + m_A(\Delta t_j)C_A + V_{CO_2}(\Delta t_j)C_{CO_2} + C_q + C_{Soft})(q_i \Delta t_j)(1 + i)^{t_j}$$

**Equation 5-5**

where  $m(\Delta t_j)$  is the quantity of injected barrels during time step  $\Delta t_j$ , the subscripts P, Sur, and A stand for polymer, surfactant, and alkali, respectively,  $V_{CO_2}(\Delta t_j)$  is the volume of  $CO_2$  per injected barrel during time step  $\Delta t_j$ , and  $q_i$  is the injection rate during  $\Delta t_j$ .

The cost of treating the recovered oil during time step  $\Delta t_j$ ,  $J(\Delta t_j)$ , is

$$J(\Delta t_j) = C_t N_p(\Delta t_j)(1 + i)^{t_j}$$

**Equation 5-6**

The expense for water disposal during time step  $\Delta t_j$ ,  $W(\Delta t_j)$ , is

$$W(\Delta t_j) = C_{WD} (q_p \Delta t - N_p(\Delta t_j)) (1 + i)^{t_j}$$

**Equation 5-7**

where  $q_p$  is the production rate during  $\Delta t_j$ .

The maintenance cost during time step  $\Delta t_j$ ,  $M(\Delta t_j)$ , is calculated as

$$M(\Delta t_j) = n C_M \Delta t_j (1 + i)^{t_j}$$

**Equation 5-8**

where  $n$  is the total number of injection and production wells for the entire EOR project.

The economic model developed for this work treats initial expenses as a function of the number of new wells that will be needed based on the scale of the project and the initial well spacing of existing wells. An overall expense is then applied per new

necessary well. For example a 5,000-acre field that initially had 40-acre well spacing during a water flood may need a 20-acre well spacing, requiring approximately 250 new wells. If one assumes 1.5 million dollars per new well, then the upfront cost is \$375 million.

The initial upfront cost,  $U$ , is

$$U = bC_1(1 + i)^{t_i}$$

**Equation 5-9**

where  $b$  is the number of new production and injection wells for the project and  $t_i$  is the time of the well constructions relative to the initiation of the EOR project.

### 5.3.3 Net Profit

Based on Equation 5-3 through Equation 5-8, the profits during time step  $\Delta t_j$ ,  $P(\Delta t_j)$ , is simply

$$P(\Delta t_j) = E(\Delta t_j) - T(\Delta t_j) - I(\Delta t_j) - J(\Delta t_j) - W(\Delta t_j) - M(\Delta t_j)$$

**Equation 5-10**

### 5.3.4 Cumulative Discounted Cash Flow

Finally, the cumulative discounted cash flow, CDCF, of the project at time  $t$  is

$$CDCF(t_j) = \sum_{j=1}^z \left[ \frac{P(\Delta t_j)}{(1 + d)^{t_j}} \right] - \frac{U}{(1 + d)^{t_i}}$$

**Equation 5-11**

where  $z$  is the number time intervals between the beginning of the project and time  $t_j$ .

The model follows the CDCF through time and selects the max value that is realized after chemical injection is completed. It is assumed that engineers working at the project will continuously monitor the profitability of the project carefully and will select to terminate the project when the project is no longer profitable based on an assumed oil price that is reasonable for the foreseeable future.

#### **5.4 Discussion of the Economical Cap**

The decision analysis applies a profit cap for both the WF and EOR. It is based on the amount that is invested in the project with taxes and royalties neglected. The cap is designed to take into account the fact that the economic model neglects external economic, political, and social factors that typically limit the max profits that a company or individual can experience on an investment. The cap is a factor of the total investment, where a 100% cap means that the total earnings, after taxes, are equal to the total investment. For the analyses discussed in this chapter, the cap factor accounts for the time value of money where the time period of interest is when the peak profit is realized.

To demonstrate how the cap is applied, an example is shown in Table 5-4. All values in the table are in terms of present value worth. In both scenarios 1 and 2 the project has \$1.155 billion dollars of expenses with a 200% cap and therefore the limit for the profits is set at \$1.155 billion dollars. For scenario 1 the total profits experienced, after taxes and royalties, is \$466 million, which is under the cap. Therefore, the selected value used in the decision analysis is \$466 million. In scenario 2 the profits are \$1.546

billion which is larger than the cap limit and therefore the cap is selected for the decision analysis.

**Table 5-4 Example of the Economic Cap**

Scenario	Cap	Total Costs	Total Earnings	Total Taxes and Royalties	Total Profits	Cap Profit Limit
	%	\$MM	\$MM	\$MM	\$MM	\$MM
1	200	1155	1964	344	466	1155
2	200	1155	3274	573	1546	1155

### 5.5 Example of the Economic Model

Figure 5-1 is an example of results from the economic model for a surfactant flood. Figure 5-2 is a plot of the oil production rate versus time in this example.

The most significant expense for the flood is associated with the cost of injecting the surfactant. The project does not become profitable until about five years after initiation. After payout, the project continues to make money until the oil production rate falls below 500 BPD or an oil cut of less than two percent, which represents the economic limit. At this point it is assumed that the project is terminated as profits can no longer be realized based on the oil price and escalation factors assumed.

**Figure 5-1 Example of Economic Model Predicting NPV**

**Figure 5-2 Oil Production Rate Associated with Figure 5-1**

## **CHAPTER 6: SENSITIVITY ANALYSIS**

### **6.1 Introduction**

The economic model and the simplified enhanced oil recovery method (SEORM) together use dozens of parameters that all influence the monetary value of an enhanced oil recovery (EOR) project's financial outcome. It is important to understand how the parameters influence the value and behavior of an EOR project. A sensitivity analysis studies the magnitude of influence a value has on the outcome of a model. The results indicate how much influence the uncertainty a parameter has on the economic value. The results also provide insight about which input parameters requires the most user attention, how the model performs, and what the range of potential outcomes are. The objection of this chapter is to identify the critical parameters in order to improve the efficiency of the decision analysis.

### **6.2 Sensitivity Analysis Process**

A local sensitivity analysis is an analysis that studies the sensitivity of the outcome to each parameter (Singh et al. 2007).

The outcomes are characterized by the maximum cumulative discounted cash flow (CDCF), as discussed in Chapter 5. The maximum CDCF, also referred to as the maximum net present value (MNPV) of the project, removes certain issues that may arise if the value of a project at a certain time is considered instead. For example, some parameters may cause the outcomes to experience early peak profitability, while other

parameters may create significant delay in peak profitability; if the selected time of interest is too early, the project's peak value may be missed. Therefore, this analysis considers the entire life of the project.

The sensitivity analysis is related to a base case to appreciate the magnitude of influence a variable has on the MNPV. The base case is presented in section **Error! Reference source not found.** A sensitivity index,  $S_i$ , as defined by Singh et al. (2007) is expressed as follows

$$S_i = \frac{\Delta \text{MNPV}}{\text{MNPV}_{\text{Base}|i}} \left( \frac{x_{\text{Base}|i}}{\Delta x_i} \right)$$

**Equation 6-1**

where

$$\Delta \text{MNPV} = \text{MNPV}_{\text{High}|i} - \text{MNPV}_{\text{Low}|i}$$

**Equation 6-2**

$$\Delta x_i = x_{\text{High}|i} - x_{\text{Low}|i}$$

**Equation 6-3**

where  $x$  is the input value for parameter  $i$ , and the subscripts High, Low, and Base, represent the upper, lower, and base case condition respectively. The index  $S_i$  can range from negative infinity to positive infinity.

As a means to determine the influence that each parameter has on the model when compared to one another, the following relation is used

$$S'_i = \frac{|S_i|}{\sum_1^i |S_i|}$$

**Equation 6-4**

where  $S'_i$  is the magnitude influence of parameter  $i$ .  $S'_i$  can range from zero to one. If the model was equally sensitive to every parameter, then each  $S'_i$  would be equal.

Each type of EOR flood, surfactant-polymer (SP), alkali-surfactant-polymer (ASP), and CO<sub>2</sub>, is analyzed separately because each flood has unique input parameters and base cases. For each flood there are from 23 to 29 parameters.

The sensitivity indices for the parameters are classified into four groups (High, Moderate, Low, and None). Table 6-1 summarizes the rating ranges. To put the  $S'_i$  values in perspective, an  $S'_i$  value of 0.1 would mean the parameter accounts for 10% of the overall impact that all of the parameters together have on the outcome. If there are 20 parameters, then the parameter would also be two times more influential than the average of all parameters.

**Table 6-1 Sensitivity Classification System**

Range	Rating
$S'_i > 0.1$	High
$0.05 < S'_i < 0.1$	Moderate
$0.02 < S'_i < 0.05$	Low
$S'_i < 0.02$	--

### 6.3 Base Cases

A base case is required to be able to establish a standard from which to measure the amount of deviation created by an input.

### 6.3.1 Review of the input variables

Table 6-2 is a summary of all of the input parameters for SEORM, the economic model, and other design parameters. The parameters listed in the table are those that are used to describe flood behavior and economic cash flows directly. They are sorted to show for which flood types they are applicable.

All input values for SEORM are based on ranges and mean values determined from the model validation, Chapter 4. The input values for the economic parameters, based on ranges from the literature, are summarized in Chapter 5. It is assumed for the analysis that SP floods and ASP floods will behave the same, therefore their SEORM values will be the same. However, CO<sub>2</sub> floods typically behave differently from SP and ASP floods. In particular the values for the specific shock velocity of the oil bank,  $v_{oB}$ , and the well spacing can vary significantly. Therefore, the values for the bases cases are similar between SP and ASP, but CO<sub>2</sub> is significantly different. For more details about the listed parameters, refer to Chapters 3 and 5.

The Koval factor for the flow between the injected chemical bank and the mobilized oil bank,  $K_2$ , depends on  $v_{oB}$  and the Koval factor for the flow between the mobilized oil bank and the initial bank,  $K_1$ . Therefore, to assist with the analysis, a factor term, referred to as  $K_f$ , is used in place of altering  $K_2$  alone. The term  $K_f$  scales  $K_2$  so that it falls between  $K_1$  and  $K_{2,max}$ . Equation 6-5 shows how  $K_2$  is calculated from  $K_f$ .

$$K_2 = K_1 + K_f(K_{2,max} - K_1)$$

**Equation 6-5**

where

$$K_{2,\max} = \frac{K_1 v_{oB}}{v_c}$$

**Equation 6-6**

and  $v_c$  is the specific shock velocity of the injected chemical bank. When  $K_f$  is zero,  $K_2$  equals  $K_1$ , and when  $K_f$  equals one,  $K_2$  equals  $K_{2,\max}$ .

There are also several other inputs required to help describe the properties of the reservoir and the field. These variables are mostly describe the generic fractional flow curve and the scale of the project. The analyses for SP and ASP are based on similar values, while CO<sub>2</sub> is significantly different. However, the values selected for each flood type do represent similar scale projects. The values for the fractional flow curves for each flood type are listed in Table 6-2. The fractional flow curves associated with the parameters are shown on Figure 6-1.

The fractional flow curves associated with the parameters are provided in Table 6-3. The only difference is for the assumed oil viscosity because CO<sub>2</sub> typically only is applied to oils of very low viscosity compared to ASP and SP floods. These values are based on interpreted averages from real field data, Chapter 4.

**Table 6-2 Base Case Input Parameters and Values for SEORM and the Economic Model**

Model	Flood	Par.	Description	Units
SEORM	All	$\Delta S_o$	Change in oil saturation over life of EOR flood	--
		$K_1$	Koval factor for mobilized oil & initial banks	--
		$K_f$	Scale factor for determining $K_2$	--
		$v_{oB}$	Specific shock velocity of mobilized oil bank	--
		$q_i$	Injection rate (constant for entire flood)	STB/day
		$q_p$	Production rate (constant for entire flood)	STB/day
		$V_p$	Total pore volume of reservoir	RB
Flood Design	All	WS	Well spacing	Acres
	SP & ASP	$V_{poly}$	Polymer slug size	$V_p$
		$Z_{poly}$	Polymer concentration	ppm
		$V_{chem}$	Surfactant or alkali slug size	$V_p$
		$Z_{sur}$	Surfactant concentration	% conc.
	ASP	$Z_{alk}$	Alkali agent concentration	% conc.
	CO <sub>2</sub>	$V_{CO2}$	CO <sub>2</sub> slug size	$V_p$
		$Z_{CO2}$	CO <sub>2</sub> WAG ratio	--
Economic Model	All	$P_o$	Price of Oil	\$/STB
		$R_E$	Escalation Factor	%/yr.
		$T_s$	Severance Tax	%
		$T_v$	Ad-Valorem Tax	%
		$T_R$	Royalty	%
		$i$	Inflation	%/yr.
		$d$	Discount Rate	%/yr.
		$C_q$	Fluid Injection Cost	\$/STB
		$C_T$	Oil Treatment Cost	\$/STB
		$C_{WD}$	Water Disposal Cost	\$/STB
		$C_l$	Start Up Cost	\$/well
		$C_M$	Maintenance Cost	\$/day/well
	SP & ASP	$C_p$	Polymer Price	\$/lbm

**Figure 6-1 Fractional Flow Curves for Each Flood Type as Based on Table 6-3 (SP and ASP Flood on the Left and CO<sub>2</sub> Flood on the Right)**

### 6.3.2 Base Case Plots

From the values in Table 6-2 and Table 6-3, the base case plots showing oil cut, oil saturation, oil recovery, and CDCF are created for each flood type. Figure 6-2 through Figure 6-5 show these plots. SEORM values for SP and ASP floods are assumed to be the same, therefore the oil cut, oil saturation plots, and oil recovery plots are all the same. All plots of CDCF depict the economics of the project from initiation to about 2500 days (SP and ASP floods) or 4000 days (CO<sub>2</sub> floods). The MNPV and the time at which oil production ends are also depicted.

**Figure 6-2 Plot of Oil Cut against Dimensionless Time for the Base Cases**

**Figure 6-3 Plot of Oil Saturation against Dimensionless Time for the Base Cases**

Figure 6-4 Plot of Oil Recovery against Time for the Base Cases

Figure 6-5 Plot of CDCF against Time for the Base Cases

The high cost of performing an SP flood is relatively high compared to the others; SP floods have more economic obstacles, which are discussed in the subsequent sections. Also, the flood life expected for a CO<sub>2</sub> flood is longer than others.

## **6.4 Sensitivity Analysis of Surfactant-Polymer Floods**

### **6.4.1 Setup for Surfactant-Polymer Floods**

The input variables used for the SP flood analysis are summarized in Table 6-4. The table includes the assumed base values and upper and lower limits for a range of values that are evaluated for each parameter. The range is assumed to be one standard deviation from the base and the standard deviations are assumed.

**Table 6-4 Summary of All Inputs Used for the SP Flood Sensitivity Analysis**

#	Var.	Base	Std. Dev.	Range			Units
1	$\Delta S_o$	0.10	0.03	0.08	-	0.13	--
2	$K_1$	2.00	0.50	1.50	-	2.50	--
3	$K_f$	0.75	0.20	0.55	-	0.95	--
4	$v_{oB}$	2.60	0.60	2.00	-	3.20	--

16	$T_V$	5.0	1.3	3.8	-	6.3	%
17	$T_R$	14.5	3.5	11.0	-	18.0	%
18	$i$	5.0	1.3	3.8	-	6.3	%/yr.
19	$d$	10.0	2.5	7.5	-	12.5	%/yr.
20	$C_q$	0.10	0.03	0.08	-	0.13	\$/ STB
21	$C_T$	0.10	0.03	0.08	-	0.13	\$/STB
22	$C_{WD}$	0.15	0.04	0.11	-	0.19	\$/ STB
23	$C_l$	1.00E+06	2.50E+05	7.50E+05	-	1.25E+06	\$/well
24	$C_M$	200	50	150	-	250	\$/day/well
25	$C_p$	1.00	0.25	0.75	-	1.25	\$/lbm
26	$C_{Sur}$	2.00	0.5	1.50	-	2.50	\$/lbm

## **6.4.2 Results for the Surfactant-Polymer Flood Analysis**

Table 6-5 is a summary of the results for the analysis. Of the original 26 parameters analyzed, 13 are somewhat sensitive. The two most sensitive parameters contribute about 25% of the sensitivity when compared to the other parameters. This result suggests that about a quarter of the variability in MNPV can be attributed to only two of the 26 parameters. Of the sensitive parameters, four are associated with SEORM and nine are economic parameters.

### **6.4.2.1 Change in Oil Saturation**

Figure 6-6 through Figure 6-9 are plots of the oil cut, oil saturation, oil recovery, and CDCF for varying  $\Delta S_o$ . The change in oil saturation,  $\Delta S_o$ , is a sensitive parameter because it influences several critical characteristics of the flood. The most important property that  $\Delta S_o$  captures is the volume of oil recovered. Large  $\Delta S_o$  implies that a large volume of oil is recovered. Altering  $\Delta S_o$  only has a marginal effect on increasing the life of the flood; therefore, larger  $\Delta S_o$  causes an increase in oil cut, which leads to faster oil recovery and higher rate of profits over the life of the flood.

**Table 6-5 Summary of Results for the Sensitivity Analysis for SP Floods**

#	Variable	$S'_i$	Rating
1	$\Delta S_0$	0.123	High
2	$K_1$	0.056	Moderate
3	$K_f$	0.024	Low
4	$v_{OB}$	0.007	--
5	$q_i$	0.031	Low
6	$q_p$	0.006	--
7	$V_p$	0.085	Moderate
8	WS	0.071	Moderate
9	$V_{Poly}$	0.007	--
10	$Z_{Poly}$	0.012	--
11	$V_{Chem}$	0.100	Moderate
12	$Z_{Sur}$	0.095	Moderate
13	$P_O$	0.131	High

Figure 6-8 Plot of Oil Recovery against Time for Varying  $\Delta S_0$  for SP Floods

Figure 6-9 Plot of CDCF against Time for Varying  $\Delta S_0$  for SP Floods

#### 6.4.2.2 Total Pore Volume

Figure 6-10 through Figure 6-13 are plots of the oil cut, oil saturation, oil recovery, and CDCF for varying  $V_p$ . The total pore volume,  $V_p$ , of the reservoir is a sensitive parameter because of how it influences the total recovered volume of oil. A large  $V_p$  value implies that a larger volume of oil can be recovered. Furthermore, the life of the flood increases significantly. The oil cut and the oil saturation, when compared against dimensionless time, do not change from the base case; however, if compared against dimensioned time, then both the oil cut and oil saturation plots become stretched horizontally. Therefore, times to oil breakthrough, peak oil cut, and sweep out occur at later periods as the pore volume increases.

Figure 6-10 Plot of Oil Cut against Time for a Varying  $V_p$  for SP Floods

Figure 6-11 Plot of Oil Saturation against Time for a Varying  $V_p$

Figure 6-12 Plot of Oil Recovery against Time for a Varying  $V_p$  for SP Floods

Figure 6-13 Plot of CDCF against Time for a Varying  $V_p$  for SP Floods

#### 6.4.2.3 Price of Oil

Figure 6-14 is a plot of the CDCF for varying oil price. The price of oil,  $P_o$ , is the most sensitive parameter for SP floods. This result is not surprising as the parameter is the most critical economic input since it directly impacts the profits of a project. Altering the price of oil has no impact on the oil cut, oil saturation, or oil recovery. It does influence the economic limit for the oil cut, thereby altering the volume of profitable oil that can be recovered. For example, a high oil price allows for profitable oil recovery at a lower oil cut. In general, the extra oil recovered between a high oil price condition and a low one is significant.

Figure 6-14 Plot of CDCF against Time for Varying  $P_o$  for SP Floods

#### 6.4.2.4 Well Spacing

Figure 6-15 and Figure 6-16 are plots of the oil recovery and CDCF for varying well spacing, WS. Well spacing is a sensitive parameter because it influences the expenses of and life of a project. Smaller values imply that the field will have more new wells installed, leading to higher upfront expenses for installation and higher maintenance expenses. More wells also increases the injection rate for the entire field, shortening the expected life of the flood by increasing the rate of oil recovery. The higher recovery rate can be beneficial since there is an earlier monetary return on the project, though the benefit typically does not outweigh the added expenses. Furthermore the model and the analysis do not take into account the potential benefit that a smaller well spacing may

induce a higher  $\Delta S_o$  because of better sweep through the reservoir. For each well spacing value,  $\Delta S_o$  is kept constant.

Figure 6-15 Plot of Oil Recovery against Time for a Varying WS for SP Floods

Figure 6-16 Plot of CDCF against Time for Varying WS for SP Floods

#### 6.4.2.5 Surfactant Expenses

The cost of injecting the surfactant is the most significant expense, and three parameters directly influence the magnitude of the expense. Altering either the slug size,  $V_{\text{Chem}}$ , or the surfactant concentration,  $Z_{\text{Sur}}$ , has a similar effect on the profitability of the project because they change the volume of the injected surfactant. The cost of surfactant,  $C_{\text{Sur}}$ , controls the cost of the surfactant. Together, the three parameters account for about 25% of the sensitivity when compared to the other parameters.

Figure 6-17 and Figure 6-18 compare how varying the volume of the injected surfactant alters the economics of an EOR project. Changing  $V_{\text{Chem}}$  alters the duration of the chemical injection; while changing the concentration alters the rate the expense is applied. Therefore, the means used to inject the volume of surfactant can influence early economics slightly, which is why  $V_{\text{chem}}$  is a bit more sensitive than  $Z_{\text{sur}}$ .

The economic model is sensitive to the cost of the surfactant because of the high volume required during injection. Varying the cost is analogous to varying the concentration because they both alter the rate of the expense. For this reason the results in Figure 6-18 are very similar to those in Figure 6-19.

In terms of this sensitivity analysis, the three parameters only influence economics and not the behavior of the flood. It can be argued that a higher volume of injected surfactant will result in higher  $\Delta S_o$ ; however, the  $\Delta S_o$  is assumed to be constant when analyzing the parameters.

Figure 6-17 Plot of CDCF against Time for Varying  $V_{Chem}$  for SP Floods

Figure 6-18 Plot of CDCF against Time for Varying  $Z_{Sur}$  for SP Floods

Figure 6-19 Plot of CDCF against Time for Varying  $C_{Sur}$  for SP Floods

#### 6.4.2.6 Heterogeneity Factors

Figure 6-20 through Figure 6-23 are plots of oil cut, oil saturation, oil recovery, and CDCF for varying  $K_1$ . Recall from section 6.3.1 that  $K_2$  will vary as  $K_1$  varies. The  $K_2$  parameter influences the declining portion of the oil cut curve. It is expected that the parameters that capture the heterogeneity and mobility of the fluids would be important, since they control the behavior of the flood. However, the Koval factors,  $K_1$  and  $K_2$ , do not alter any expenses or earnings economically, or the total oil recovered, therefore the sensitivity of the parameters is somewhat limited. They do alter the rate of profits through the life of the flood which is how the MNPV is influenced.

Changes to  $K_1$  directly impacts the peak oil cut experienced as well as the life of the flood. High Koval values suggest floods with lower peak oil cuts and longer lives. A

high Koval value suggests significant channeling and therefore also experiences an earlier breakthrough time.

Figure 6-20 Plot of Oil Cut against Dimensionless Time for a Varying  $K_1$  for SP Floods

Figure 6-21 Plot of Oil Saturation against Dimensionless Time for a Varying  $K_1$  for SP Floods

Figure 6-22 Plot of Oil Recovery against Time for a Varying  $K_1$  for SP Floods

Figure 6-23 Plot of CDCF against Time for a Varying  $K_1$  for SP Floods

Figure 6-24 and Figure 6-25 are plots of the oil cut and CDCF for varying  $K_f$ . The parameter  $K_f$  controls  $K_2$ , but it is not as influential as  $K_1$  because the range of values that  $K_2$  can take is controlled by  $K_1$ ,  $v_{oB}$ , and  $S_{oF}$ . The parameter  $K_f$  is only a factor that selects a value for  $K_2$  between  $K_1$  and  $K_{2,max}$ . Altering  $K_f$  does alter the early oil cut and the life of the flood; however, the changes translate to a minimal change in MNPV for the project. A lower  $K_f$  is a desirable condition because it suggests a more even flow through the life of the flood.

**Figure 6-24 Plot of Oil Cut against Dimensionless Time for a Varying  $K_f$  for SP Floods**

Figure 6-25 Plot of CDCF against Time for a Varying  $K_f$  for SP Floods

#### 6.4.2.7 Least Sensitive Parameters for the Simplified Enhanced Oil Recovery

##### Method

The parameters  $v_{oB}$ ,  $q_i$ , and  $q_p$  had very little influence on the MNPV for SP floods. Figure 6-26 and Figure 6-27 are plots of the oil and CDCF for varying specific shock velocity of the oil bank,  $v_{oB}$ . The  $v_{oB}$  parameter controls the break through time and the upper limit for  $K_2$ . A higher  $v_{oB}$  implies an earlier break through time and a longer flood life. However,  $v_{oB}$  has minimal influence on the oil cut over the life of the flood and therefore does not appreciably alter the MNPV.

Figure 6-26 Plot of Oil Cut against Dimensionless Time for a Varying  $v_{oB}$  for SP Floods

Figure 6-27 Plot of CDCF against Time for a Varying  $v_{oB}$  for SP Floods

The low sensitivity of the injection and production rates,  $q_i$  and  $q_p$ , is surprising because they are expected to influence the dimensioned time behavior of the flood. Figure 6-28 is a plot of the CDCF for varying  $q_p$ , and Figure 6-29 and Figure 6-30 are figures of oil cut and CDCF against time for varying  $q_i$ , respectively. The only rate to be a factor of any degree is  $q_i$  because SEORM relates oil production to injection rate, including oil cut. Therefore the production rate does not influence the time scale of the project or the rate of recovery. Altering the production rate has a minor influence on the economics because a higher production rate suggests a larger volume of water must be treated.

The sensitivity of the results to the injection rate is limited because even though the rate of oil recovery and life of the flood can be varied, the volume of recovered oil and expenses are not. The analysis suggests that the desirable condition is for the injection rate to be as high as allowable because a higher injection rate leads to an earlier response in oil cut.

Figure 6-28 Plot of CDCF against Time for Varying  $q_p$  for SP Floods

Figure 6-29 Plot of Oil Cut against Time for a Varying  $q_i$  for SP Floods

Figure 6-30 Plot of CDCF against Time for a Varying  $q_i$  for SP Floods

#### 6.4.2.8 Upfront and Maintenance Expenses

Both the upfront cost,  $C_I$ , and maintenance cost,  $C_M$ , are strictly economic parameters that are directly related to the number of wells in the field.  $C_I$  is a onetime expense based on the number of new wells that must be installed for the project. Figure 6-31 is a plot of the CDCF for varying  $C_I$ .  $C_M$  is a daily rate that is applied to every well in the field. Figure 6-32 is a plot of the CDCF for varying  $C_M$ . Both expenses are not very significant when compared against surfactant costs, hence their low sensitivity.

Figure 6-31 Plot of CDCF against Time for a Varying  $C_1$  for SP Floods

Figure 6-32 Plot of CDCF against Time for a Varying  $C_M$  for SP Floods

#### 6.4.2.9 Ad-Valorem Tax

Figure 6-33 is a plot of the CDCF for a varying ad-valorem tax,  $T_V$ . The parameter  $T_V$  appeared to have some influence on the MNPV of a SP flood.  $T_V$  is only applied if the field exists on property owned by the oil producing company, otherwise only royalties are considered. The tax should be considered as a parameter with some uncertainty because even though the tax rate may be well established, the value of the property could vary, leading to variations in taxes. The sensitivity of the tax is small because the total expense it generates is small when compared against the cost of the surfactant.

Figure 6-33 Plot of CDCF against Time for a Varying  $T_V$  for SP Floods

## 6.5 Sensitivity Analysis of Alkali-Surfactant-Polymer Floods

### 6.5.1 Setup of Analysis of Alkali-Surfactant-Polymer Flood Analysis

The ASP floods have similar parameters as SP floods. Therefore the ranges provided in Table 6-4 remain applicable for the most part. All variation and inclusions to Table 6-4 are listed in Table 6-6. The ranges were determined the same way as before for the SP flood analysis in Section 6.4. The ASP flood analysis accounts for a total of 29 parameters.

**Table 6-6 Summary of Additional Inputs to Table 6-4 Used for the ASP Flood Sensitivity Analysis**

#	Var.	Base	Std. Dev.	Range			Unit
11	$V_{\text{Chem}}$	0.40	0.10	0.30	-	0.50	$V_p$
12	$Z_{\text{Sur}}$	0.30	0.075	0.23	-	0.38	% conc.
27	$Z_{\text{Alk}}$	1.00	0.25	0.75	-	1.25	% conc.
28	$C_A$	0.40	0.10	0.30	-	0.50	\$/lbm
29	$C_{\text{Soft}}$	0.75	0.18	0.57	-	0.93	\$/ STB

### 6.5.2 Results for the Surfactant-Polymer Flood Analysis

The results of the sensitivity analysis for ASP flood parameters are summarized in Table 6-7. Of the 29 parameters analyzed, 14 showed at least some sensitivity. Many of the parameters that are sensitive for the SP flood are also about equally sensitive for ASP floods. Notable parameters that did not experience much change in sensitivity include  $K_I$ ,  $K_f$ ,  $v_{oB}$ ,  $q_i$ ,  $WS$ ,  $T_V$ ,  $T_R$ ,  $C_I$ , and  $C_M$ . The sensitivity of  $\Delta S_o$ ,  $V_p$ , and  $P_o$  increased a bit, while the sensitivity of  $V_{\text{Chem}}$ ,  $Z_{\text{Sur}}$ , and  $C_{\text{Sur}}$  decreased significantly. The changes in sensitivity are direct results of decrease in the overall influence of the cost injecting

surfactant because there is less surfactant. The injected alkali is also relatively cheap compared to the surfactant and therefore the total cost of injection is lower. The lower injection expenses results in lower sensitivity for any parameter associated with injection costs and higher sensitivity for other parameters.

For ASP floods,  $V_{\text{Chem}}$  is still a moderately sensitive variable because it directly controls the volume of injected chemicals for both the surfactant and alkali agent. Any parameter that controls the cost of injection of the chemicals has low sensitivity. These parameters include  $Z_{\text{Sur}}$ ,  $C_{\text{Sur}}$ ,  $Z_{\text{Alk}}$ , and  $C_{\text{Alk}}$ .

The parameter  $T_R$  is the royalty tax. Even though  $T_R$  did register some sensitivity, it is not noteworthy because the royalty for a project should be a well understood value that does not often fluctuate with time. Therefore, the parameter will not be treated as one with uncertainty when going into the decision analysis.

Plots of all of the parameters for ASP floods are similar to those shown for SP floods and can be found in Appendix C.

**Table 6-7 Summary of Results for the Sensitivity Analysis for ASP Floods**

## **6.6 Sensitivity Analysis of CO<sub>2</sub> Floods**

### **6.6.1 Setup of CO<sub>2</sub> Flood Analysis**

For the CO<sub>2</sub> flood analysis, many of the parameters discussed in the previous analyses continue to apply with the same ranges as mentioned earlier. However, CO<sub>2</sub> floods tend to behave differently and thus must be setup differently. The most significant differences are with  $v_{oB}$  and WS. CO<sub>2</sub> floods tend to experience higher  $v_{oB}$  values and are designed for higher WS. Table 6-8 is a complete summary of all of the inputs and the ranges analyzed.

**Table 6-8 Summary of Inputs Used for CO<sub>2</sub> Flood Sensitivity Analysis**

#	Var.	Base	Std. Dev.	Range		Unit
1	$\Delta S_o$	0.10	0.03	0.08	- 0.13	--
2	$K_1$	3.50	1.0	2.50	- 4.50	--
3	$K_f$	0.80	0.20	0.60	- 1.00	--
4	$v_{oB}$	6.00	1.50	4.50	- 7.50	--
5	$q_i$	1000	250	750	- 1250	STB/day
6	$q_p$	1000	250	750	- 1250	STB/day
7	$V_p$	2.00E+08	5.00E+07	1.50E+08	- 2.50E+08	RB
8	WS	30	7	23	- 37	Acres
9	$V_{CO_2}$	0.75	0.25	0.50	- 1.00	$V_p$

22	$C_M$	200	50	150	- 250	\$/day/well
23	$C_{CO_2}$	4.00	1.0	3.00	- 5.00	\$/MCF

### 6.6.2 Results of CO<sub>2</sub> Flood Analysis

The results of the sensitivity analysis are summarized in Table 6-9. Of the 23 parameters studied, 14 exhibited at least some sensitivity. There is some change in the degree of sensitivity for a few of the parameters when compared to the results from the

ASP and SP analyses. The parameters  $V_P$  and  $P_o$  are significantly more important than for the other flood types, while  $\Delta S_o$  is less important. The  $\Delta S_o$ 's importance diminished somewhat because both the WAG ratio ( $Z_{CO_2}$ ) and  $\Delta S_o$  have a direct impact on  $v_C$  and therefore impact on the shape of the oil history curve.  $\Delta S_o$  is more influential than the WAG ratio because it also impacts the total volume of oil that is recovered. The significant reduction in the influence of parameter  $\Delta S_o$  and the overall reduction in expenses for  $CO_2$  lead to a higher relative influence for  $V_P$  and  $P_o$  when compared against other parameters. The lower expenses are a direct result of lower injection costs, fewer wells for maintenance, and fewer new wells that need to be drilled.

Most of the analyzed parameters behave and alter the base case in the same manner as for the other flood types. Only  $\Delta S_o$  and  $Z_{CO_2}$  act differently than for the other flood types because of how both influence  $v_C$  and  $K_2$ . Plots of all of the parameters for  $CO_2$  floods are similar to those shown for SP floods and can be found in Appendix C.

**Table 6-9 Summary of Results for the Sensitivity Analysis for CO<sub>2</sub> Floods**

#	Variable	$S_i$	Rating
1	$\Delta S_o$	0.067	Moderate
2	$K_1$	0.077	Moderate
3	$K_f$	0.039	Low
4	$v_{oB}$	0.048	Low
5	$q_i$	0.045	Low
6	$q_p$	0.003	--
7	$V_p$	0.133	High

17	$d$	0.015	--
18	$C_q$	0.006	--
19	$C_T$	0.000	--
20	$C_{WD}$	0.011	--
21	$C_l$	0.019	--
22	$C_M$	0.029	Low
23	$C_{CO_2}$	0.059	Moderate

## 6.7 Summary of the Sensitivity Analysis

Table 6-10 is a summary of the most sensitive parameters ordered from most to least sensitive. All of the flood types produced relatively similar results.

The most critical parameters for each flood type are the price of oil, change in oil saturation, and total pore volumes because each of these variables have direct impact on the total earnings of a project. The price of oil scales the profits for a project, while the change in oil saturation and total pore volumes impact the total volume of oil that could be recovered for profit.

The next most influential parameters for all flood types are the well spacing and Koval factor between the oil bank and initial bank,  $K_1$ . Both of these parameters have the largest impact on the rate of recovery. Earlier recovery of the oil leads to a better profit margin. The parameters  $K_f$ , specific shock velocity of the oil bank, injection rate act in a similar manner, but to a lesser extent.

Of the design parameters, the slug size and concentration of the injected chemicals are influential. For the surfactant-polymer and alkali-surfactant-polymer floods it is the expense generated by larger volumes of injected chemicals that is influential, while for  $\text{CO}_2$  floods it is the technical concept that the WAG ratio influences the recovery history.

The economic expenses in general are not very sensitive parameters. All flood types are equally dependent on  $T_V$ ,  $C_I$ ,  $C_M$ , and  $T_R$ . Even though each flood showed some sensitivity to  $T_R$ , it can be ignored as a parameter with influential uncertainty because the royalty rate should be well known going into a project. The only expense that has a considerable impact on the profitability of a project is the total cost of the surfactant for SP floods because the cost and volume of the required chemical is very

expensive. This expense is controlled by chemical slug size, the concentration of surfactant, and the cost of surfactant. These parameters are also moderately sensitive for ASP flood analyses because of the small volume of surfactant used.

**Table 6-10 Summary of Results for the Sensitivity Analysis of All Flood Types**

Variable	$S_i$				Rating	Comments
	SP	ASP	CO <sub>2</sub>	Average		
P <sub>O</sub>	0.131	0.153	0.193	0.159	High	
$\Delta S_o$	0.123	0.144	0.067	0.112	High	
V <sub>p</sub>	0.085	0.103	0.133	0.107	High	
V <sub>Chem</sub>	0.100	0.059		0.079	Moderate	Important for SP floods
WS	0.071	0.083	0.065	0.073	Moderate	
K <sub>1</sub>	0.056	0.066	0.077	0.066	Moderate	Increase with importance as expenses decrease
Z <sub>Sur</sub>	0.095	0.028		0.061	Moderate	Important for SP floods
C <sub>Sur</sub>	0.095	0.028		0.061	Moderate	Important for SP floods
V <sub>CO2</sub>			0.060	0.060	Moderate	
C <sub>CO2</sub>			0.059	0.059	Moderate	
q <sub>i</sub>	0.031	0.037	0.045	0.038	Low	
Z <sub>CO2</sub>			0.035	0.035	Low	
C <sub>I</sub>	0.037	0.043	0.019	0.033	Low	
K <sub>f</sub>	0.024	0.028	0.039	0.030	Low	
T <sub>R</sub>	0.024	0.028	0.035	0.029	Low	

All of the parameters in Table 6-10 can be considered in a decision analysis because the uncertainty of their values could alter the decision. The only parameter that can be neglected from Table 6-10 for a decision analysis is T<sub>R</sub>.

## **CHAPTER 7: SET UP OF DECISION ANALYSIS FRAMEWORK FOR ENHANCED OIL RECOVERY**

### **7.1 Introduction**

A decision analysis allows one to evaluate a decision that involves parameters with uncertainty. For example, enhanced oil recovery (EOR) is usually only profitable if the oil price is high. However, oil price is very difficult to predict because it is based on global economies and energy demands (Belhaj and Lay 2008). A decision analysis applies probabilities to various outcomes as a means to account for the uncertainty. From the assessed probabilities and associated outcomes, one can evaluate whether or not implementing an EOR project is preferred. This chapter discusses the construction of a decision analysis framework that is used to evaluate the value of a pilot for an EOR project.

### **7.2 Background on Decision Making Process**

Deterministic decision making compares the outcome of each alternative and determines the most favorable outcome. The chosen alternative either maximizes satisfaction or minimizes dissatisfaction (Ang and Tang 2007). A decision analysis is made up of different parts including events, probabilities, alternatives, and outcomes.

An event is an occurrence that alters the outcome of a decision (Ang and Tang 2007). For example an increase in the value for the price of oil is an event. An event

could also represent a combination of occurrences, such as a high oil price and low final oil saturation. The success of an EOR project hinges on the outcome of numerous events.

Probabilities are used to characterize the likelihood of an occurrence of an event relative to all other possible mutually exclusive events in the same sample space. The value of a probability is between zero and one, and the sum of probabilities for all mutually exclusive events that comprise the space is equal to one. The set of probabilities for a sample space is called a probability distribution. The distributions can also be described by either a probability mass function (PMF) or a probability density function (PDF). PMFs are applied to discrete sample spaces and PDFs are applied to continuous sample spaces. Figure 7-1 contains examples of a PMF and PDF. With PMFs, each listed event is associated with a value and the probability for the value is the PMF. For PDFs, the area under the curve between two values gives the probability for an event between the two bounding values (Ang and Tang 2007).

**Figure 7-1 Examples of a PMF (Left) and PDF (Right)**

A decision is made from a set of alternatives. Examples of alternatives include performing continued water flooding (WF) or implementing EOR. An outcome is a

consequence of a selected alternative and the combination of events that occurs when that alternative is implemented. Generally, consequences are quantified with utility values, where the more preferable the outcome the greater the utility value. For this study, the utility values are expressed as the maximum net present monetary values based on the results from the simplified enhanced oil recovery method (SEORM) and the economic model.

### **7.2.1 Decision Trees**

A decision tree is a graphical representation of the decision making process. It lays out the events, probabilities, alternatives, and outcomes associated with the decision. In a decision tree, square nodes are decision nodes, which denote points where a decision maker makes a decision. Circular nodes are chance nodes, which represent points of uncertainty. Branches that extend from the decision nodes are alternatives and branches that extend from chance nodes are events. The expected utility for an alternative is the summation of the products of the respective probability and utility value for each event (Ang and Tang 1984). Figure 7-2 demonstrates how the different components of a decision tree fit together. Equation 7-1 is an example of the calculation of the expected utility for an alternative.

Figure 7-2 Basic Decision Tree (Namhong 2008)

$$E(u_{A_1}) = P(S_1)u_{1|1} + P(S_2)u_{1|2} + \cdots + P(S_j)u_{1|j} + \cdots + P(S_m)u_{1|m}$$

**Equation 7-1**

### 7.3 General Discussion of the Enhanced Oil Recovery Decision

This thesis project studies two decisions. One decision, known as the prior decision, is a decision made based on existing information. For the thesis the prior decision is between WF and EOR without any pilot test information. The other decision is the preposterior decision, which is a decision to determine whether or not to obtain additional information. For the thesis, the preposterior is between performing a pilot test and not performing a pilot test.

Pilot tests are small scale-field projects designed to predict the behavior a larger-scale field project. In regards to EOR, they are intended to provide information on the potential of a large-scale project by allowing for better predictions of events.

The events that define the utility values are the input parameters for SEORM and the economic model. As discussed in Chapter 6, there are several sensitive parameters for SEORM and the economic model. For this project, the decision analysis focuses on the three most sensitive parameters for typical EOR projects, the change in oil saturation ( $\Delta S_o$ ), total pore volume ( $V_P$ ), and price of oil ( $P_o$ ). From this point forward, the discussion focuses on a decision involving these three parameters. The analysis can be expanded to include more parameters in future work.

### **7.3.1 The Model for the Water Flood Alternative**

The WF alternative is modeled with a simple decline curve analysis. Several options exist for producing a decline curve, including hyperbolic, exponential, and harmonic equations (Walsh and Lake 2003). Each would produce similar results because under most circumstances it is the end of the water flood life is being modeled. Therefore, the simplest approach, an exponential curve, was selected for the model.

For the exponential decline curve analysis it is assumed that the decline rate,  $D$ , remains constant. The oil production rate for the water flood,  $q_{WF}$ , is

$$q_{WF}(t) = q_{WF|i} e^{-Dt}$$

**Equation 7-2**

where  $t$  is time in terms of years,  $q_{WF|i}$  is the initial oil production rate at the start of the water flood in terms of STB/year, and  $D$  is in terms of %/year. The cumulative recovery,  $N_P$ , can be found by

$$N_P = \frac{(q_{WF|i} - q_{WF})}{D_i}$$

**Equation 7-3**

where  $N_P$  is in units of STB (Walsh and Lake 2003).

It is assumed that the curve begins with a 100% oil cut at the start of the water flood and that it declines to an oil cut that exists at the time that the EOR decision is to be made. Also, it is assumed that the total production rate does not change over time. Based on these assumptions, an assumed age of the water flooding for the field is back calculated. Oil production is assumed to continue until either an economic limit is reached or until the water flood residual oil saturation,  $S_{or}$ , is reached. Figure 7-3 is an example decline curve of the oil cut over time for a WF analysis. The economic model discussed in Chapter 5 is also applied to find the utility of the WF alternative.

**Figure 7-3 Plot of an Example Decline Curve used in the WF Analysis**

Figure 7-4 is an example plot of the cumulative discounted cash flow (CDCF) for a water flood, starting at the point when a decision is to be made. The CDCF is based on Equation 4-11. The max net present value (MNPV) is marked to represent the point at which peak profits would be realized. This point coincides with the economic limit point in Figure 7-3. The curve experiences a decline because of two factors. The first is that profits are outweighed by costs, and second is that the cumulative value declines with time. The factors are analogous to those that influence the CDCF for EOR.

**Figure 7-4 Plot of an example CDCF for a WF Analysis**

The WF analysis is sensitive to  $V_P$  and  $P_o$ , but not  $\Delta S_o$ .  $V_P$  alters the assumed volume of the reservoir that is being flooded and therefore impacts the life and ultimate recovery of the WF. The WF utility is also sensitive to  $P_o$  because it directly influences the earnings for a project. The parameter  $\Delta S_o$  has no impact on the WF analysis because  $\Delta S_o$  is related to the residual oil saturation altered by the EOR process.

## 7.4 Construction of the Decision Tree Structure for the Analysis

The following is a discussion of the decision tree used in the decision analysis for the thesis project and the meaning of the different components of the tree.

### 7.4.1 Construction of the Prior Decision Tree

A prior decision is a direct comparison of the utilities of alternatives and it is based on assessed probabilities of events (Min 2008). The analysis is between WF and EOR. If the expected utility for the EOR alternative is greater than the expected utility of the WF alternative, then the analysis suggests that performing an EOR project is the preferable decision. Figure 7-5 is the decision tree of the prior analysis with the three uncertain parameters.

Figure 7-5 The Decision Tree for the Prior Analysis

## 7.4.2 Construction of the Posterior and Preposterior Decision Trees

A decision that accounts for new information is known as a posterior decision. The posterior decision uses Bayes' theorem for adjusting probabilities.

### 7.4.2.1 Posterior Decision Tree

A posterior decision provides insight in how new information can alter a decision (Min 2008). For example, one pilot result may suggest that EOR is preferable while another may suggest that WF is preferable. Figure 7-6 is an example of a generic decision tree for a posterior analysis.

Figure 7-6 Generic Posterior Decision Tree (Min 2008)

New information from a pilot would be included in a posterior tree. Pilots provide some information for some events. For example, a pilot could give some insight on  $\Delta S_o$  and  $V_P$ , but no information about  $P_o$ . A decision tree for a posterior analysis must properly include pilot information. Figure 7-7 is part of the decision tree for the posterior analysis of  $\Delta S_o$ ,  $V_P$ , and  $P_o$ . There are still chance nodes for the  $\Delta S_o$  and  $V_P$  events because pilot information is typically imperfect, and, therefore, there is still some uncertainty about the occurrence of the events.

A preposterior decision is used to analyze the value of information (VOI) for new information. VOI is defined as the cost of the pilot such that the expected utility of performing the pilot test is equal to that if no additional information is obtained. For this analysis, the VOI of the pilot is the difference in the expected net present values of the “No Pilot” and “Pilot” alternatives. The VOI ranges from zero to an upper bound defined by the value of perfect information (VPI). The VPI means that the pilot perfectly predicts the  $\Delta S_o$  and  $V_P$  values with certainty. If the VOI is equal to zero then the pilot provides no added benefit. If the VOI is a high value, especially if it is much greater than the actual cost of a pilot test, then it suggests that the information from the pilot is expected to be worthwhile (Ang and Tang 1984).

## **7.5 Non-Informative Prior Probabilities**

The prior, posterior, and preposterior decisions are all sensitive to the initial probabilities that are assessed for the events. In this work, the starting point for assessing probabilities assumes complete ignorance, which is the state of complete uncertainty. Probabilities under the assumption of complete uncertainty are known as non-informative probabilities (Namhong 2008). Available field information is then included to update the starting point distribution to represent the point in time when the EOR and or pilot decision is made.

A common way of handling non-informative probabilities is to follow the principle of insufficient reason (Gilbert et al. 2010). The principle of insufficient reason (PIR) suggests that if there is complete uncertainty about the likelihood of an event then

the event should have a uniform probability distribution. A uniform probability distribution assumes that all events are equally likely. The idea is also known as equiprobability. The challenge in implementing PIR is establishing what sample space to which apply it.

### **7.5.1 Principle of Insufficient Reason Applied to Input**

Typically, PIR is applied to the input of a decision problem, but in a manner that is not rational or consistent. A new concept is to apply PIR to the output of the decision, which provides for rational and consistent results. These two approaches are discussed in the following sections.

#### **7.5.1.1 Rationality**

At first glance it may difficult to imagine that PIR applied leads to irrational results; however, it can produce unintended user bias when creating a probability distribution. The user may not apply a bias to likeliness of a particular event, but he or she may show preference to a choice. To better illustrate this issue an example is presented. This example and all subsequent examples assume a surfactant-polymer (SP) flood.

Assume the decision analysis for choosing between EOR and WF is based solely on the possible events for  $P_o$ . Four possible values for  $P_o$  are assumed; \$60/STB, \$80/STB, \$100/STB, \$120/STB. The decision tree for the analysis is shown in Figure 7-9. Figure 7-10 is a plot of the preferential probabilities of EOR and WF.

**Figure 7-9 Decision Tree for Simple Example Demonstrating Bias in the Principle of Insufficient Reason**

**Figure 7-10 Preferential Outcome Plot for the Simple Example Demonstrating Bias**

From the analysis the WF alternative is selected for three quarters of the events and EOR is selected for only a quarter of the events. By assigning equal probabilities to each possible  $P_o$ , the decision maker makes the WF alternative more likely to be preferred. Therefore, following PIR unintentionally creates bias in the decision because

the decision maker neglects the uncertainty in the decision output when creating a probability distribution for the events.

#### 7.5.1.2 Consistency

Another drawback to applying PIR to the input is that it can create inconsistent probability distributions that vary based on how the events are designated. The following example illustrates this issue.

For SP floods, two other important parameters are the surfactant slug size,  $V_{Sur}$ , and the concentration of surfactant in the slug,  $Z_{Sur}$ . These two parameters are about equally influential parameters according to the sensitivity analysis because they both directly influence the amount of injected surfactant, which will be referred to as  $m_{Sur}$ . Equation 7-4 is the relationship of  $m_{Sur}$  to  $V_{Sur}$  and  $Z_{Sur}$ .

$$m_{Sur} = V_{Sur}Z_{Sur}V_P(351 \text{ lbm/STB})$$

**Equation 7-4**

where  $V_P$  is the total pore volumes of the reservoir in units of STB. The units for  $V_{Sur}$  are in fraction of  $V_P$ ,  $Z_{Sur}$  are in percent of the concentration, and  $m_{Sur}$  are in lbm.

There are two ways to apply PIR to account for the economic influence that the injected surfactant has on an SP flood. One approach would be for a decision maker to assume equal probability values for  $m_{Sur}$  and the other would be to assume equal probability values for both  $V_{Sur}$  and  $Z_{Sur}$ . If the decision maker assumes that  $V_{Sur}$  is either 0.2  $V_P$  or 0.3  $V_P$  and  $Z_{Sur}$  is either 2% conc. or 3% conc., then there would be three possible  $m_{Sur}$  values, 1.4 $V_P$  lbm/STB, 2.1 $V_P$  lbm/STB, and 3.2 $V_P$  lbm/STB.

Figure 7-11 is a summary of the different probability distributions based on the possible assumptions. Different probability distributions result depending on how PIR is applied. These types of inconsistencies could lead to significantly different utility values for each alternative and ultimately alter the decision.

(a) Probability Distribution based on a Uniform Distribution for  $m_{Sur}$

(b) Probability Distribution based on Uniform Distributions for  $V_{Sur}$  and  $Z_{Sur}$

Figure 7-11 Demonstration of Inconsistent Probability Distributions Created by Selectively Applying PIR to Input Parameters

A thorough analysis takes into account all possible events so that every possible preference outcome can be realized. For many decision analyses, a continuous number of events are required to represent all events. Analytical solutions are necessary to accurately handle a continuous number of events. Creating analytical solutions can be difficult unless simple equations are used to describe the utility outcomes for each alternative. Therefore, for complicated decision analyses, a decision maker must rely on numerically-based results. A continuous state can be mimicked by studying as many distinct events as possible. Furthermore, for many problems the ranges of values for events would be between negative and positive infinity unless there are boundaries.

An issue with PIR is that it is sensitive to the selected range for an event and the selected number of events studied within that range. An example of this problem can be observed when considering the parameter  $V_P$ . If one truly follows the assumptions of complete uncertainty then one has to recognize that  $V_P$  can range between zero and infinity. It is not possible to study a  $V_P$  equal to infinity, therefore the example looks at a case that ranges between zero and one billion RB. If a decision maker divides the range between into four intervals and another divides it into six intervals, and both apply PIR then they would get different probabilities for each alternative. Table 7-1 is a summary of the results the two analyses and Figure 7-12 is plot of the probability distributions for the outcomes for each analysis.

**Table 7-1 Comparison of Two Analyses that Subdivide a Range of  $V_p$  Differently**

	$V_p$ Event, MMRB	Utilities, \$MM		Selection
		EOR	WF	
Four Events	125	-243	132	WF
	375	-45	136	WF
	625	164	137	EOR
	875	363	142	EOR
Six Events	83	-272	124	WF
	250	-148	133	WF
	417	-11	136	WF
	583	129	139	WF
	750	266	142	EOR
	917	395	141	EOR

**Figure 7-12 Comparison of the Decision Outcomes for Two Analyses that Divide a Range of  $V_p$  Differently**

By comparing the two analyses it can be seen that the final decision can be altered by simply changing the number of events selected for study within a range of values. Therefore the probability distribution for a continuous number of events could be significantly different from a discrete set of events. This paradox implies a user could

create unwanted bias by predetermining a range of values for each event and by selecting how many events are studied within the range.

Furthermore, applying PIR to the input does not allow a user to truly account for an infinitely wide range. Referring back to the previous example, at about 600 MMRB the decision switches from WF to EOR. This means for any  $V_P$  value greater than 600 MMRB, EOR is the preferable choice. If the sample range is set between zero and infinity, then the probability that the WF would be selected goes to zero because it is defined by a limited range and the EOR selection has no limits. Using PIR for a range of input values with an infinite number of events and no limits could create a decision where one alternative approaches a probability of 100%.

### **7.5.2 The Decision-Based Method**

The bias, inconsistency, and instability created by applying PIR to the input can lead to non-informative prior probabilities that may vary from user to user. Non-informative priors should be consistent between decision makers, otherwise similar analyses would produce varying results and potentially cause confusion. Therefore, a robust approach is necessary for establishing the prior distributions. The decision-based method (DBM) attempts to resolve these issues (Min 2008, Gilbert et al. 2010).

#### **7.5.2.1 Theory of the Decision-Based Method**

DBM is based on the principle that decision making under complete ignorance should be unbiased and the randomness is with the decision maker's choice and not the input. Therefore, the method applies PIR to the possible preference outcomes, rather than

directly to the possible input values. This approach allows for the probability distribution of the preference outcomes to be uniform, regardless of the number of events, as long as new preference outcomes are not created (Gilbert et al. 2010). For example, in the decision between EOR and WF there are three possible preference outcomes:

$$\text{EOR} > \text{WF}$$

$$\text{WF} > \text{EOR}$$

$$\text{EOR} \sim \text{WF}$$

**Equation 7-5**

where “>” denotes the preference of one alternative to another and “~” denotes indifference between alternatives. Each of these outcomes have an equal probability,  $1/3$ , assigned to them as long as the events allow them to occur. Figure 7-13 shows three different cases that help illustrate the basis of DBM.

Alt.	Events		
	E <sub>1</sub>	E <sub>2</sub>	E <sub>3</sub>
EOR	500	150	-100
WF	200	150	100

(a) Case 1

Alt.	Events		
	E <sub>1</sub>	E <sub>2</sub>	E <sub>3</sub>
EOR	500	250	-100
WF	200	175	100

(b) Case 2

Alt.	Events			
	E <sub>1</sub>	E <sub>2</sub>	E <sub>3</sub>	E <sub>4</sub>
EOR	500	150	-100	-200
WF	200	150	100	75

(c) Case 3

**Figure 7-13 Cases that Illustrate the Basis for DBM**

In Case 1, there are three events and all three possible preferential outcomes shown in Equation 7-5 occur. Case 2 is a slight alteration of Case 1 where only two preferential outcomes occur,  $\text{EOR} > \text{WF}$  and  $\text{WF} > \text{EOR}$ . These two cases would have a different probability distribution for the preferential outcomes because the number of possible preferential outcomes is different. Case 3 is similar to Case 1 with an added event. Both Cases 1 and 3 have the same probability distribution despite having different

events. A comparison of these three cases, as shown in Figure 7-14, illustrates that it is the outcome of the events and not the number of events that controls the distribution for the preferential outcomes.

**Figure 7-14 Comparison of the Probability Distributions for the Preferential Outcomes for the Example in Figure 7-13**

DBM can be extended to include  $n$  alternatives as shown in Equation 7-6, if all of the preference outcomes are assumed to be mutually exclusive and collectively exhaustive.

$$\begin{aligned}
&A_1 > \\
&A_2 > \\
&\vdots \\
&A_n > \\
&A_1 \sim A_2 > \\
&A_1 \sim A_3 > \\
&\vdots \\
&A_{n-1} \sim A_n > \\
&\vdots \\
&A_1 \sim A_2 \sim A_3 > \\
&\vdots \\
&A_1 \sim A_2 \sim \dots \sim A_n >
\end{aligned}$$

**Equation 7-6**

The maximum number of preference outcomes,  $\Omega$ , is

$$\Omega = 2^n - 1$$

**Equation 7-7**

If all of the preference outcomes exist for a given decision, then the probability of each outcome according to PIR are equally likely and be defined as the inverse of  $\Omega$  (Min 2008).

Once the probabilities of the preference outcomes are established, the probabilities of the events are determined. Once again PIR is invoked. Each preference outcome is divided by similar sets of outcome utilities. The sets of outcome utilities are treated as equally likely. Each utility set is also subdivided and the events that make up them up are treated as equally likely (Gilbert et al. 2010). Table 7-2 is an example that demonstrates how the probabilities for events are assigned based on the outcomes.

**Table 7-2 Decision Matrix Demonstrating How Event Probabilities are Determined**

		Events							
		E <sub>1</sub>	E <sub>2</sub>	E <sub>3</sub>	E <sub>4</sub>	E <sub>5</sub>	E <sub>6</sub>	E <sub>7</sub>	E <sub>8</sub>
Alt. Uti.	EOR	600	350	125	-100	-100	-100	-100	-400
	WF	175	150	125	100	100	100	75	50
Prob.	Event	1/6	1/6	1/3	1/27	1/27	1/27	1/9	1/9
	Uti. Set	1/6	1/6	1/3	1/9			1/9	1/9
	Pref. Out.	1/3		1/3	1/3				
Pref. Out.		EOR > WF		EOR ~ WF	EOR < WF				

For the example in Table 7-2, there are three preference outcomes: EOR > WF, EOR ~ WF, and EOR < WF. The variable E stands for an event, and U stands for a utility set. For the EOR > WF preference, there are two sets of utility values (EOR, WF): U<sub>1</sub> = (600, 175) and U<sub>2</sub> = (300, 150). Based on the concept of randomness, each of these outcomes would be equally likely. The probability U<sub>1</sub> would equal U<sub>2</sub> and the sum of the probabilities would equal the probability of EOR > WF. U<sub>1</sub> consists of only E<sub>1</sub> and therefore the probability of E<sub>1</sub> is equal to the probability of U<sub>1</sub>. The same applies for E<sub>2</sub> and U<sub>2</sub>. These relationships are summarized by Equation 7-8 through Equation 7-11.

$$P(\text{EOR} < \text{WF}) = P(U_1) + P(U_2) = 1/3$$

**Equation 7-8**

$$P(U_1) = P(U_2) = 1/6$$

**Equation 7-9**

$$P(E_1) = P(U_1) = 1/6$$

**Equation 7-10**

$$P(E_2) = P(U_2) = 1/6$$

**Equation 7-11**

where P stands for the probability of an outcome or event. For the EOR ~ WF preference outcome, there is only one utility set,  $U_3 = (125, 125)$ , and there is only one event,  $E_3$ , that can lead to the preference outcome. Therefore

$$P(\text{EOR} \sim \text{WF}) = P(U_3) = P(E_3) = 1/3$$

**Equation 7-12**

Finally, for the preference outcome  $\text{EOR} < \text{WF}$ , there are three distinct utility sets and there are five events that lead to the preference outcome. The utility sets are  $U_4 = (-100, 100)$ ,  $U_5 = (-100, 75)$ , and  $U_6 = (-400, 50)$ . Utilities  $U_5$  and  $U_6$  are associated with one event and  $U_4$  is associated with three. Following the same process as before

$$P(\text{EOR} < \text{WF}) = P(U_4) + P(U_5) + P(U_6) = 1/3$$

**Equation 7-13**

$$P(U_4) = P(U_5) = P(U_6) = 1/9$$

**Equation 7-14**

$$P(U_4) = P(E_4) + P(E_5) + P(E_6) = 1/9$$

**Equation 7-15**

$$P(E_4) = P(E_5) = P(E_6) = 1/27$$

**Equation 7-16**

$$P(U_7) = P(E_7) = 1/9$$

**Equation 7-17**

$$P(U_8) = P(E_8) = 1/9$$

**Equation 7-18**

**Figure 7-15 Comparison of the Probability Distribution for DBM and PIR for the Example in Table 7-2**

By following DBM and keeping strictly to the probabilities that are established, the expected utilities for each alternative change when compared to applying PIR to the inputs. Table 7-3 is a summary of the comparison of expected values for the two methods. DBM suggests that the decision maker would select the EOR alternative while the PIR applied to the input prefers the WF alternative.

**Table 7-3 Comparison of DBM and PIR in Terms of the Expected Utilities**

Assumption	Alternative Utilities	
	EOR	WF
Decision Based Method	133	121
Principle of Insufficient Reason	34	109

Another observation from the previous example is that DBM suggests a higher likelihood for  $E_3$  than any other event. The method's emphasis of  $E_3$  implies that the event is significant to the decision. DBM increased the weight for  $E_3$  to maintain a uniform probability distribution for the preference outcomes. By giving more weight to

certain events, it allows a decision maker to pick out the events of interest and determine how the final decision can be affected by them.

The probability distributions created with DBM also suggest that the parameters are not necessarily independent. Therefore, the probability for a given set of events that involves multiple parameters is not simply the product of the marginal probabilities of each parameter.

#### **7.5.2.2 Example of DBM Dealing with Rationality and Consistency**

DBM was introduced because of issues with unintended bias and inconsistency which are inherent with PIR. The example shown in Figure 7-11 will be used to demonstrate how DBM overcomes these issues. Table 7-4 and Table 7-5 summarize the probabilities determined with DBM assuming that the events are either defined by  $V_{\text{Sur}}$  and  $Z_{\text{Sur}}$  or  $m_{\text{Sur}}$ . Recall that  $m_{\text{Sur}}$  is related to  $V_{\text{Sur}}$  and  $Z_{\text{Sur}}$  as shown in Equation 7-4. Figure 7-16 is a collection of the probability distributions common for the results from both Table 7-4 and Table 7-5.

Regardless of which set of events are used to approach the decision, the probabilities are the same and thus consistency is maintained. Furthermore, the probability distribution of the preference outcomes is uniform and therefore there is no bias between the choices.

**Table 7-4 Decision Matrix Assuming the Events are Defined by  $V_{Sur}$  and  $Z_{Sur}$**

		Events							
		E <sub>1</sub>		E <sub>2</sub>		E <sub>3</sub>		E <sub>4</sub>	
		V <sub>Sur</sub>	Z <sub>Sur</sub>	V <sub>Sur</sub>	Z <sub>Sur</sub>	V <sub>Sur</sub>	Z <sub>Sur</sub>	V <sub>Sur</sub>	Z <sub>Sur</sub>

(b) Probability Distribution of  $m_{Sur}$

(c) Probability Distribution of the Preference Outcomes

**Figure 7-16 Plots of Probability Distributions**

To demonstrate that DBM can handle a continuous distribution and an infinite range, the issue discussed in section 7.5.1.2 will be used as an example.  $V_P$  is taken from zero to a hundred billion RB. Dividing a hundred billion RB into even intervals would create very large intervals unless a very large number of intervals were used. It is already

shown that DBM can handle inconsistency and therefore considering  $V_P$  or the  $\log(V_P)$  would produce the same result for the same range of values studied. By using  $\log(V_P)$ , the low values of  $V_P$  as well as the high ones can be considered. Figure 7-17 is a plot that compares how the number of intervals influence the PDF for  $\log(V_P)$  when using DBM. As the number of intervals increases, the resolution of the PDF improves and approaches a constant shape.

**Figure 7-17 Comparison of the PDF for DBM with Varying Intervals**

Table 7-6 is a comparison of the expected utilities for the different intervals. As the number of intervals approaches infinity, the expected utility approaches a constant.

**Table 7-6 Comparison of the Expected Utilities for DBM with Varying Intervals**

Number of Intervals	Decision Based Method	
	EOR	WF
25	-2829	164
50	-3193	179
100	-3161	187

Even though the decision looks at a very wide range of possible events, the probability of one alternative being selected over another remains the same because the preference outcomes are assumed to be equally likely. Therefore, DBM is able to handle a range with limits at positive and negative infinity.

Therefore, the problems that exist when PIR is applied to inputs have been addressed with DBM.

### **7.5.3 Applying Monte Carlo Simulation to the Decision Based Method**

When working with DBM and input parameters that come from a continuous space, the calculus of analytically deriving the continuous joint probability distribution can be cumbersome. This problem is especially true when dealing with multiple input parameters at a time. Applying Monte Carlo simulation provides a method to work around the problem.

Monte Carlo simulation is a technique that uses random sampling to create a representative sample of events (Ang and Tang 2007). For example, if a probability distribution exists, then Monte Carlo simulation can be applied to randomly select a set of events based on the probability distribution for simulations. Monte Carlo is used at different stages of the decision analysis process because many simulations must be performed.

To apply Monte Carlo simulation to DBM, the following procedure is followed. The first step is to assume that all of the inputs have a uniform probability distribution. A random number generator is then used to select values for each parameter. Each selected

set represents one sample. For each sample set of input parameters, outcomes for EOR and WF are calculated. Several samples are collected and the number of preferential outcomes, the number of outcome sets, and the number of events for each outcome set is then calculated. In order to be able to keep track of all of the samples, especially when working with multiple input parameters, each parameter range is divided into a certain number of intervals. Again, the larger the number of intervals is per parameter, the better the resolution for the probability distribution. The sample sets are organized into the intervals and then probabilities are determined with DBM for only sampled intervals. For example, if  $\log(V_P)$  is divided into 100 intervals and a Monte Carlo simulation is run with 50 samples, then only the intervals represented by the selected samples are used in DBM. This example is also illustrated in Figure 7-18. The Monte Carlo simulation is able to capture the generic shape of the distribution and produce relatively similar expected values as shown in Table 7-7.

**Table 7-7 Comparison of the Expected Values for a Monte Carlo Simulation and a Complete Analysis**

	<b>Decision Based Method</b>	
	<b>EOR (\$MM)</b>	<b>WF (\$MM)</b>

100 Intervals (50 MC Simulations)	-3325	185

**Figure 7-18 Comparison of the Monte Carlo Simulation and a Complete Analysis**

## 7.6 Bayes' Theorem

As new information is obtained, such as production history up to the EOR decision, an EOR pilot test, research, etc., the probability distributions for events may be updated. Bayes' theorem is applied to update existing information. For this study, the probability distributions are updated at several points. One point is to update the non-informative probability distribution based on any experience or knowledge about the field or EOR process. Another point is to update the probability distributions again based on new information determined from the results from the pilot tests.

### 7.6.1 Bayes' Theorem Definition

Bayes' theorem is used to relate new information to an existing probability of a sample space, as shown in

$$P(A_i|I_j) = \frac{P(I_j|A_i)P(A_i)}{P(I_j)}$$

**Equation 7-19**

where  $P(A_i|I_j)$  is the updated probability of event  $A_i$  given the information  $I_j$ ,  $P(A_i)$  is original probability of event  $A_i$ ,  $P(I_j|A_i)$  is the likelihood function that relates the probability distribution of  $A$  and  $I$  to each other, and  $P(I_j)$  is the probability of the information about event  $A_i$ . Based on the total probability theorem,  $P(I_j)$  is defined to be

$$P(I_j) = \sum_{i=1}^i P(I_j|A_i)P(A_i)$$

**Equation 7-20**

The updated probability is also known as the posterior probability and is based on the original probability and the likelihood function (Ang and Tang 2007).

The likelihood function acts like a filter that is used to narrow the original distribution based on the new information. The probability of every possible event in the likelihood function ranges between zero and one. There are two limiting cases for the function, no new information and perfect information. If the likelihood distribution is uniform, then it is suggested that there is no new information that alters the original probability distribution. If the likelihood distribution applies a probability of one to a particular event but zero to all others, then it suggests perfect information, and the updated distribution only has the event occurring.

The limiting cases can offer some good information; however, it is not reasonable to assume either limiting case for a decision analysis because a pilot or any source of

information will provide some input, but not perfect input. For this study, an example likelihood function is used for illustrative purposes.

### 7.6.2 Bayes' Theorem Example

The following is an example of Bayesian application. A field is being assessed for EOR. There is some understanding about the field's  $V_P$  from previous measurements and experience with the field. Figure 7-19 is the initial probability distribution. An EOR pilot is then performed and it appears the original prediction for  $V_P$  needs to be adjusted. A likelihood function, Figure 7-20, is then developed and applied to the initial distribution. The adjusted posterior probability is shown in Figure 7-21. The new probability distribution is different from the original distribution and so is the expected outcome. The expected  $V_P$  shifts from 350 MMRB for the prior distribution to 267 MMRB for the posterior distribution.

Figure 7-19 Prior Probability Distribution for the Bayes' Theorem Example

**Figure 7-20 Likelihood Function from Testing for the Bayes' Theorem Example**

**Figure 7-21 Posterior Probability Distribution for the Bayes' Theorem Example**

## 7.7 Summary

The decision analysis for this study involves several decisions including one between enhanced oil recovery and continued water flooding and a “Go” versus “No Go” for a pilot. This study focuses on three parameters,  $\Delta S_o$ ,  $P_o$ , and  $V_p$  because they are the

most influential parameters based on the sensitivity analysis of the simplified enhanced oil recovery method and the economic model, which are used to determine the value of any outcome. The method and construction of the decision framework discussed in this chapter could allow one to expand the decision analysis to account for more parameters.

An important step in the decision analysis is to establish non-informative prior probabilities so that a starting point can be set for the probability distribution of all of the events. It is pointed out that simply assuming all events for input parameters are equally likely and assuming arbitrary ranges of values for the events is not an adequate approach because it creates inconsistent probability distribution between users. Therefore the decision based method is recommended and applied to the decision analysis.

The probabilities established with the decision based method can then be adjusted or updated with either existing or new information through the use of Bayes' theorem. From the decision based method and Bayes' theorem, every probability distribution for every part of the decision can be determined. Chapter 8 discusses the entire decision making process step by step with a simple example.

## **CHAPTER 8: EXAMPLE OF THE DECISION ANALYSIS**

### **8.1 Introduction**

This chapter provides a generic discussion as to how to perform a decision analysis that uses the decision based method (DBM) to create non-informative prior probabilities and adapt those probabilities with Bayes' theorem. The example discussed in this chapter focuses on three parameters, ultimate change in oil saturation ( $\Delta S_o$ ), price of oil ( $P_o$ ), and total pore volumes ( $V_p$ ). The selected ranges for each parameter are divided into five intervals. Five intervals are used to keep the example simple and easy for demonstrative purposes.

### **8.2 Performing the Decision Analysis for the Thesis Decision**

A generic procedure is presented for performing the analysis through two similar examples. Example A works with a non-informative probability distribution for the prior decision, and assumes a perfect pilot. Example B works through with an informed probability distribution for the prior decision and assumes perfect information from the pilot. The three input parameters,  $\Delta S_o$ ,  $V_p$ , and  $P_o$ , define the events for the decision. The alternatives are enhanced oil recovery (EOR) and continued water flooding (WF). The following outlines the steps taken and any additional assumptions made throughout the analysis.

### **8.3 Outline for Example A**

#### **8.3.1 Step 1: Setup the Decision Tree**

The first step is to setup the decision tree for the decision analysis. Construction of the decision tree is discussed in Chapter 7. A decision tree establishes the frame work of the decision. The decision for this study is a preposterior decision that looks at a “Go,” “No Go” decision for a performing a pilot. A preposterior decision also involves a prior decision and posterior decisions.

#### **8.3.2 Step 2: Establish the Conditions for the Enhanced Oil Recovery Decision**

The next step is to determine the generic conditions for the EOR decision, which entails assuming values to use for the parameters in the simplified enhanced oil recovery method (SEORM), the economic model, and the water flood model, as shown in Table 8-1. Only parameters that are involved in the analysis do not have to be assumed. Table 8-2 is a summary of the values used in the example.

**Table 8-1 Summary of Inputs for the Decision Analysis**

Model	Flood	Par.	Description	Units
SEORM	All	$\Delta S_o$	Change in oil saturation over life of EOR flood	--

					Cap for WF: 300%		

### 8.3.3 Step 3: Establish the Non-Informative Prior Probability Distributions for the Analyzed Parameters

The non-informative prior probability distribution is determined with the decision based method (DBM). DBM is recommended to avoid bias or other issues with the initial probability distributions for  $\Delta S_o$ ,  $V_p$ , and  $P_o$ .

### **8.3.3.1 Applying the Decision-Based Method to the Study's Decision**

DBM is used to determine the initial probability distributions for the events of the parameters analyzed, because of its robustness when compared to the principle of insufficient reason. The following is a discussion of how DBM is applied and the sensitivity of the probability distributions.

### **8.3.3.2 Sensitivity Analysis of the Decision Based Method**

The following explores the sensitivity of DBM by studying the parameters individually, in pairs, and all together, and the sensitivity involved with alterations to the ranges and the number of events considered. The base case values for the decision analysis are in Table 8-2. The parameters highlighted are altered in the sensitivity analysis.

There are only two preference outcomes  $EOR > WF$  and  $EOR < WF$ . The preference outcome of  $EOR \sim WF$  is not possible because it represents an infinitesimally small portion of the full outcome space since it only occurs at the intersection of the EOR utility with the WF utility. The intersection of the values of EOR and WF utilities represent a line for a surface. The overlap represents an infinitesimally small area on the surface. Therefore, there is a zero chance of the indifference outcome occurring. The sensitivity analysis looks to see how different step intervals and the parameters influence the prior probability distributions.

### 8.3.3.3 Sensitivity of Parameter Intervals

The complete sample space for the parameters cannot be captured by a discrete number of events. Instead each parameter is assumed to be defined by a continuous set of events. The ranges of the sets must include all possible values between the bounding conditions or to infinity in the positive and negative directions. For the analysis, large values are used to represent infinity. Table 8-3 is a summary of the ranges used in the analysis. The parameters  $\Delta S_o$  and  $V_P$  are not taken down to zero because errors occur with SEORM.

**Table 8-3 Summary of the Starting Ranges Used in the Sensitivity Analysis of DBM**

Parameter	Physical Ranges		Analysis Range		Units
	Lower Bound	Upper Bound	Lower Bound	Upper Bound	
$\Delta S_o$	0	0.35	0.01	0.35	--
$P_o$	0	$\infty$	1	1.0E+8	\$/STB
$V_P$	0	$\infty$	1	1.0E+11	RB

The log of parameter  $V_P$  and  $P_o$  are divided into intervals because a very large range of values is being considered. For each parameter, 25, 50, and 100 step intervals are studied. Figure 8-1 and Figure 8-2 are plots that demonstrate the sensitivity for  $\Delta S_o$  and  $P_o$ , respectively. It appears that at 100 intervals there is not significant change and that 50 intervals is a good approximation of a continuous set.  $V_P$  is not represented because for all possible events where  $V_P$  is the only changing input parameter, the utility value of EOR is never greater than the utility value of the WF, as shown in Figure 8-3.

**Figure 8-1 Plot Comparing the Interval Steps for the Parameter  $\Delta S_0$**

**Figure 8-2 Plot Comparing the Interval Steps for the Parameter  $P_0$**

**Figure 8-3 Plot Comparing the Utility Values for Parameter  $V_P$**

Even though no value of  $V_P$  alters the decision when it is considered solely, it does become a factor when more parameters are included in the analysis.

#### **8.3.3.4 Sensitivity of Parameter Combinations**

The simplest analyses are those involving a single parameter defining the events. For example, Figure 8-4 is a plot of both utility values for EOR and WF and the PDF for the parameter  $\Delta S_o$ . The PDF value changes at four distinct points. The first change occurs at a very low  $\Delta S_o$ , at about 0.02. Between 0.01 and 0.02, the utility set is constant because neither the utility for EOR or WF changes. Any  $\Delta S_o$  event within that range leads to the same outcome; therefore, the entire range is treated as equally likely and as a unique utility set. The EOR utility begins to rise because at  $\Delta S_o = 0.02$  there is some profit after the surfactant slug is completely injected.

The second change is when the decision switches from WF to EOR at about 0.14  $\Delta S_o$ . Between 0.02 and 0.14, all of the utility sets are considered unique, but have the same preferential outcome and, therefore, all are treated as equally likely.

The third change occurs at about  $\Delta S_o = 0.26$ , when the utility sets become constant again. Between 0.14 and 0.26 all of the utility sets have the same preferential outcome and each set is unique and treated as equally likely.

There is one last change in the PDF at  $\Delta S_o = 0.27$  because there are a few similar utility sets between 0.26 and 0.27. After 0.27, all utility sets have a similar utility value and thus each event within the range is treated as equally likely.

The PDF suggests that events between 0.02 and 0.26 are the most significant to the decision because there are many unique utility outcomes and, therefore, more uncertainty in the preference than at the ends of the distribution.

Figure 8-4 Plot of the PDF against the Utilities for  $\Delta S_o$

The marginal probability distribution of  $\Delta S_o$  changes significantly when new parameters are introduced, as shown in Figure 8-5. A marginal PDF is a PDF of single parameter with the probabilities of all other parameters consolidated. It appears that when either parameters  $P_o$  or  $V_P$  are introduced, the marginal PDF changes considerably from the case where  $\Delta S_o$  is the only parameter. The addition of parameter  $P_o$  creates a relatively linear PDF that gently slopes downward, thus no particular range of  $\Delta S_o$  values is more important to the decision. Before when  $\Delta S_o$  is the sole parameter, any event less than 0.24 leads to WF being the preferred alternative. With  $P_o$  considered, even low  $\Delta S_o$  values have the potential for conditions where EOR is preferred as long as  $P_o$  is very high. At low  $\Delta S_o$  there is a wider range of  $P_o$  where the decision may switch between WF and EOR than at high  $\Delta S_o$  values because there is a narrower range for  $P_o$  where the switch in preference occurs. Therefore, at low  $\Delta S_o$  values there is more uncertainty than at high  $\Delta S_o$  values.

If  $V_P$  is included, then the distribution changes to where there are a couple of plateaus. At low  $\Delta S_o$ , less than 0.14, it appears there are not many circumstances where the decision switches from WF to EOR and thus there is not much uncertainty as to what the preference is. At larger  $\Delta S_o$  values the range of  $V_P$  values where the switch occurs is larger and, therefore, there is more uncertainty. It appears that at about  $\Delta S_o = 0.26$ , the range of  $V_P$  values where the preference switches begin to shrink, leading to more certainty in the preferred outcome and lower PDFs. At large  $\Delta S_o$  values, it is more likely that EOR is preferred than WF, thus there is less uncertainty.

**Figure 8-5 Plot Comparing the Marginal PDFs of  $\Delta S_0$  with Various Parameter Combinations**

It is also important to study the joint PDFs of the variable combinations. Figure 8-6 and Figure 8-7 are plots of the PDF for  $\Delta S_0$  and  $\log(V_P)$ , and  $\Delta S_0$  and  $\log(P_o)$ , respectively. Both of these plots suggest that there are combinations of parameters that are not significant to the decision. For the  $\Delta S_0$  and  $\log(V_P)$  combination, any event with a  $\log(V_P)$  value that is less than six is of very low significance because regardless of what  $\Delta S_0$  is, the decision will be for WF since the  $V_P$  is too small to allow EOR to ever be more profitable than WF. Furthermore, at such low  $V_P$  the outcome sets are very similar. The most significant events are between seven and nine for  $\log(V_P)$  and 0.15 and 0.35 for  $\Delta S_0$  because this is where the largest mix of switches in preference occurs as well as the fewest similar outcome sets. For any  $\Delta S_0$  value less than 0.15 there does not appear to be scenarios where EOR is selected. When  $\Delta S_0$  is greater than 0.15 there is considerable variability in the preferred alternative because for any  $\Delta S_0$  value there is a limited range of  $V_P$  where EOR is preferred. If the field is too small, then there is not

enough oil to recover for the project to be profitable. If the field is too large, then it takes too long to recover oil profitably in terms of the time value of money.

For the  $\Delta S_o$  and  $\log(P_o)$  combination, any event that has a  $\log(P_o)$  greater than four is of minimal importance because every combination events within the range creates a condition where EOR is preferred. Furthermore, the utility sets in this range are similar. The most important events are between  $\log(P_o)$  values of zero and three. In this range of  $\log(P_o)$  value, all  $\Delta S_o$  values are significant to the decision, because EOR can be preferred for almost any  $\Delta S_o$  value as long as  $P_o$  is large enough. Therefore, there is considerable uncertainty in what the preference is.

**Figure 8-6 Joint PDF Plots of  $\Delta S_o$  and  $\log(V_p)$  Combination for Two (a) and Three (b) Parameter Analyses**

(a)  $\Delta S_0$  and  $P_0$  Analyzed

(b)  $\Delta S_0$ ,  $\log(V_P)$  and  $P_0$  Analyzed

**Figure 8-7 Joint PDF Plots of  $\Delta S_0$  and  $P_0$  Combination for Two (a) and Three (b) Parameter Analyses**

It is also important to study how the combination of all three parameters influences the distributions. Referring back to Figure 8-5, it appears that the marginal probability distribution of  $\Delta S_0$  for all three changing parameters is similar to when only  $\Delta S_0$  and  $P_0$  are changing. The distribution suggests that  $V_P$  does not alter the marginal distribution as significantly as  $P_0$ . This observation is most likely a result of how only a small range of  $V_P$  is important to the decision (between seven and nine  $\log(V_P)$ ) and for any  $V_P$  within that range, the joint PDF of  $\Delta S_0$  and  $P_0$  are likely to have similar forms. Therefore, when all joint PDFs of  $\Delta S_0$  and  $P_0$  for all  $V_P$  values are consolidated together, as shown in Figure 8-7 (b), there is similar emphasis for certain ranges of events as in Figure 8-7 (a). Both plots appear to have somewhat different shapes, but they both produce similar marginal distributions for  $\Delta S_0$  because both have emphasis on low  $\Delta S_0$  values and between  $\log(P_0)$  values of one and four.

The joint PDFs also change once all three parameters are considered in the analysis. Figure 8-6 and Figure 8-7 show the joint PDFs for analyses with three parameters as well. For the  $\Delta S_o$  and  $\log(V_P)$  joint PDF, the range of interest does not change significantly. However; the emphasis of the distributions are different. The joint PDF of  $\Delta S_o$  and  $\log(V_P)$  with  $P_o$  consolidated, Figure 8-6 (b), suggests there is higher uncertainty at lower  $\Delta S_o$  values. The uncertainty is greater because at various  $P_o$ , scenarios where a low  $\Delta S_o$  can lead to an EOR as the preferred outcome increases. Higher  $\Delta S_o$  values are less likely to have scenarios where WF is preferred over EOR than lower  $\Delta S_o$  values will have scenarios where EOR is preferred over WF.

For the  $\Delta S_o$  and  $P_o$  joint PDF there is some change when all three parameters are considered. Overall, both joint PDFs place a similar amount of emphasis in similar ranges of interest. Each  $V_P$  interval is likely have a slightly different range of interest for  $\log(P_o)$  and  $\Delta S_o$ . Therefore, the peak values for the joint PDF is reduced because consolidation of all of the  $V_P$  intervals creates a slightly more uniform distribution over the  $\log(P_o)$  range of interest.

The probability distributions for other parameter combinations can be found in Appendix D.

### **8.3.3.5 Sensitivity of Parameter Ranges**

Altering the ranges of the parameters can also have an impact on the probability distributions. As is seen in Figure 8-6 and Figure 8-7, there are regions of values where the probability approaches zero. Combinations of events that create these conditions are

essentially representing the limits to the parameters' ranges. Any combination of events that exist in the regions of zero probability is meaningless to the decision and is ignored. If these regions are removed and the ranges for the parameters are reduced, they still create probability distributions similar to the distributions based on the complete ranges. However, if the ranges are narrowed too much and important outcomes are removed, then the distributions are changed.

Table 8-4 is a summary that compares the ranges used in the sensitivity analysis. The “complete” ranges are full range of possible values, the “selected” ranges are carefully altered ranges that do not remove important combinations of events, and the “narrowed” ranges are arbitrarily altered.

**Table 8-4 Summary of the Ranges used in the Sensitivity Analysis for DBM**

Parameter	Complete Range		Selected Range		Narrowed Range	
	Low	High	Low	High	Low	High
$\Delta S_o$	0.01	0.35	0.01	0.35	0.05	0.25
$\log(P_o), \log(\$ / STB)$	0	8	0	4	1	3
$\log(V_P), \log(RB)$	0	11	6	11	7	9

Figure 8-8 is a collection of plots comparing the different ranges for  $\log(P_o)$  and  $\log(V_P)$ . The “complete” range and the “selected” ranges produce very similar results, while the “narrowed” ranges produce a significantly different distribution. The main differences between in the plots from the “complete” and “selected” ranges are a result of improved resolution because of the finer intervals for the “selected” range.

From the sensitivity analyses it appears that as long as enough intervals are used and that wide enough ranges are applied that do not eliminate important outcomes, then a consistent result can be attained.

(d) Marginal PDF Comparing Ranges

Figure 8-8 Plots Comparing the Sensitivity of DBM to the Ranges for Parameters

### 8.3.3.6 Applying Monte Carlo Simulation to the Decision Based Method with Multiple Parameters

To best recreate a continuous sample set, a numerical analysis that breaks up the range into 50 intervals is used. This involves analyzing 125,000 event combinations,

which means 125,000 simulations with SEORM. More intervals would produce more refined distributions; however, the computation time becomes a limitation and the Excel data sheet used for the calculations becomes difficult to handle. Monte Carlo simulation could be used to deal with these issues, especially as more parameters are included in the analysis.

Following the Monte Carlo procedure discussed in Chapter 7 for a single parameter, the process is expanded for multiple parameters. An example of the results is demonstrated with the previous DBM example with the “Selected” ranges for the inputs. The example works with 40,000 Monte Carlo simulations, which is a fraction of the 125,000 simulations needed for the full evaluation.

**Figure 8-9 Comparison of a Rigorous Analysis Against Monte Carlo Simulated Result for Approximating the Marginal PDF of  $\log(P_o)$**

**Figure 8-10 Comparison of a Rigorous Analysis Against Monte Carlo Simulated Result for Approximating the Joint PDF of  $\log(V_p)$  and  $\log(P_o)$**

It appears that at about 40,000 simulations relatively general representations of the probability distributions begin to form. More simulations provide considerably better resolution; however, it does provide a decent rough approximation that could be used for preliminary analyses. More plots comparing the Monte Carlo results with the full analyses are in Appendix D.

### 8.3.3.7 Summary of Sensitivity Analysis for the Decision Based Method

DBM is moderately sensitive to the number of intervals selected. For good resolution, a large number of intervals are recommended; however, this can lead computational times that may be limiting. Monte Carlo simulation can assist with this issue.

Carefully studying the distributions created with DBM can provide insight into which parameters are most influential and the parameters influence the probability

distributions. Based on the sensitivity analysis, it appears that  $P_o$  may be the most influential parameter.  $\Delta S_o$  also appears to provide relatively identifiable points where the decision typically changes.

When working with DBM, it is important to recognize how the selected ranges for each input parameter influences the probability distributions. As long as important events that alter the decision are not eliminated, similar distributions can be generated with ranges reduced from more complete ranges. It is preferred to determine an appropriate range that wide enough to capture all important events, but narrow enough to allow for good resolution.

#### **8.3.3.8 Applying the Decision Based Method for Example A**

For the example DBM is applied, with five intervals for each input parameter and 125 event combinations for all three input parameters. The range for each parameter follows the ranges used for the “selected” ranges in Table 8-4. A plot of the probability distribution is shown in Figure 8-11. In the figure, the distribution is laid out so that event can be represented.

Figure 8-11 Probability Distribution for the Non-Informative Prior Probabilities

#### 8.3.4 Step 4: Determine the Expected Utilities of the Alternatives for the Non-Informative Prior Decision

The non-informed prior probability distributions created with DBM assume there is no information about the field in any form. The expected utilities are calculated from the utilities and probabilities as shown in Equation 8-1.

$$\begin{aligned}
 u_{A_1} = & P(\Delta S_{o|1}, P_{o|1}, V_{p|1})u_{A_1|1} + \dots + P(\Delta S_{o|1}, P_{o|1}, V_{p|h})u_{A_1|h} + \dots \\
 & + P(\Delta S_{o|1}, P_{o|j}, V_{p|h})u_{A_1|h \times j} + \dots + P(\Delta S_{o|i}, P_{o|j}, V_{p|h})u_{A_1|h \times j \times i}
 \end{aligned}$$

Equation 8-1

To obtain accurate expected values, the parameters should be divided into several intervals. With the expected utilities calculated the decision is then made between WF and EOR. The alternative with the largest expected utility is the selected alternative.

For this example the expected utility for the EOR alternative is \$-959 MM and for the WF alternative it is \$115 MM, which means WF is preferred. The expected utility for EOR is so low because there is an upper cap limit set on the profits, but there is no cap to the potential losses. Furthermore, there are considerable expenses associated with SP flooding including upfront costs and high injection costs. Water flooding does not have such expenses and it is assumed that if there is no profitable recovery the water flooding is immediately terminated, which means the lowest value for WF is zero.

#### **8.3.5 Step 5: Set Up the Posterior Decision**

The posterior decision is designed to account for new information from a pilot test. For the decision analysis in this study, the pilot test provides information about  $\Delta S_o$  and  $V_P$  but no information about  $P_o$ . Therefore, the posterior analysis considers every possible combination of  $\Delta S_o$  and  $V_P$  that could be realized for the pilot. For each pilot realization, a decision between EOR and WF is analyzed. Because there is new information from the pilot, the probability distribution from the prior decision is updated. The distribution is updated through Bayes' theorem with likelihood functions.

For this example, the likelihood functions assume that the values from the pilot provide perfect information. Therefore, if the pilot suggests a value for a particular parameter, then that event is representative of what will happen for a full scale project.

These distributions only apply to  $\Delta S_o$  and  $V_P$  because no new information exists for  $P_o$ .

Instead the likelihood function for  $P_o$  is uniform.

The following demonstrates the likelihood distributions for a particular pilot realization. Consider that the results from the pilot are  $\Delta S_o$  is 0.04 and  $\log(V_P)$  is 8.5. Then the likelihood functions would be as shown in Table 8-5. The likelihood probability distribution function is shown in Figure 8-12.

**Table 8-5 Example of the Likelihood Distributions**

$\Delta S_o$	Likelihood Distribution	$\log(P_o)$ $\log(\$/STB)$	Likelihood Distribution	$\log(V_P)$ $\log(RB)$	Likelihood Distribution
0.04	1.0	0.4	1.0	6.5	0.0
0.11	0.0	1.2	1.0	7.2	0.0
0.18	0.0	2.0	1.0	8.3	1.0
0.25	0.0	2.8	1.0	9.4	0.0
0.32	0.0	3.6	1.0	10.5	0.0

**Figure 8-12 Example of the Likelihood Function**

By applying the likelihood function to the prior probability distribution through Bayes' theorem, an updated probability distribution is created for the posterior decision. This distribution is shown in Figure 8-13. The new distribution puts heavy emphasis on the event  $\Delta S_o = 0.04$ ,  $\log(V_p) = 8.5$ , and  $\log(P_o) = 2.0, 2.8$ , and  $3.6$ . There are three significant  $P_o$  values because they are emphasized in the prior probability distribution, as well, Figure 8-13.

**Figure 8-13 Example Updated Probability Distribution for the Posterior Decision**

### 8.3.6 Step 6: Determine the Expected Utilities of the Alternatives from the Posterior Analysis

The expected utility values for each posterior branch are then determined. An additional assumption involved with the posterior decision is that time passes before a pilot could be started, completed and the results analyzed. Therefore, the EOR process is delayed. The calculated EOR utilities reflect the delay and include profits made from a continued water flood and any expenses or profits involved with the pilot itself. Equation 8-2 represents the equation for calculating the utility of EOR with the pilot,

$$U_{\text{EOR|Pilot}} = U_{\text{WF during delay}} + U_{\text{Pilot}} + U_{\text{Delayed EOR}}$$

**Equation 8-2**

where  $U_{WF \text{ during delay}}$  represents earnings during the delay from continued water flooding,  $U_{Pilot}$  are the earnings or losses from the pilot project itself, and  $U_{Delayed \text{ EOR}}$  is the utility from the field EOR project with a delayed start.  $U_{Pilot}$  does not account for any costs associated with research, lab testing, publicity, or expenses associated with preparing for a pilot test. The delay does reduce the overall value of an EOR project because of decreasing value on delayed earnings. The WF utility with the pilot,  $U_{WF|Pilot}$ , includes expenses or profits from the pilot as well as the earnings from water flooding,  $U_{WF}$ .

$$U_{WF|Pilot} = U_{WF} + U_{Pilot}$$

**Equation 8-3**

The calculation of the expected value for each posterior decision is analogous to the calculation for the prior decision. Table 8-6 is a summary of the results for the posterior decisions for the example. With all of the expected utilities calculated, a decision is made for each posterior decision. Again the alternatives with the highest expected utility are selected. The EOR alternative is selected fewer times than the WF alternative. EOR is preferred for 30% of the events.

**Table 8-6 Summary of the Expected Values from Posterior Decisions for the Example**

Event, $E_j$		Expected Utilities, \$MM		Probability of Information, $P(I_j)$
$\Delta S_o$	$\log(V_p)$	EOR	WF	
0.04	6.5	-185	4	0.023
0.04	7.5	-184	43	0.033
0.04	8.5	502	254	0.033
0.04	9.5	-608	212	0.042
0.04	10.5	-3878	75	0.028
0.11	6.5	-102	4	0.054
0.11	7.5	-88	39	0.030
0.11	8.5	529	244	0.030
0.11	9.5	-1524	176	0.038
0.11	10.5	-3875	75	0.038
0.18	6.5	-55	4	0.053
0.18	7.5	-11	40	0.047
0.18	8.5	553	181	0.064
0.18	9.5	-1849	145	0.050
0.18	10.5	-3873	75	0.050
0.25	6.5	-5	4	0.066
0.25	7.5	66	41	0.045
0.25	8.5	513	157	0.055
0.25	9.5	-1274	146	0.055
0.25	10.5	-3872	75	0.063
0.32	6.5	29	4	0.021
0.32	7.5	158	43	0.021
0.32	8.5	569	157	0.021
0.32	9.5	-602	155	0.021
0.32	10.5	-3872	75	0.021

### 8.3.7 Step 7: Set Up of the Preposterior Decision

Once the prior and posterior decisions are completed, the preposterior decision is set up. The branch representing the “No Pilot” choice is simply the decision made from the prior analysis and the expected utility associated with it. The branch representing the “Pilot” choice is represented by the expected utility for the pilot. The expected utility is

the sum product of the probability of information for each pilot test and the selected expected utility values for each posterior decision. For this example, the probabilities for each pilot are shown in Table 8-6. These probabilities are determined with the total probability theorem

$$P(I_j) = \sum_{i=1}^n P(I_j|E_i)P(E_i)$$

**Equation 8-4**

where  $P(I_j)$  is the probability of information  $I$  for pilot event  $j$ , which represents a combination  $\Delta S_o$  and  $V_P$ ,  $P(I_j|E_i)$  is the probability of information  $I_j$  given event  $E_i$ , and  $P(E_i)$  is the probability for event  $E$  for event  $i$ , which represents a particular combination of  $\Delta S_o$ ,  $V_P$ , and  $P_o$ .  $P(I_j|E_i)$  is the likelihood function for the pilot's information and  $P(E_i)$  is from the prior probabilities. Based on the conditions used for this example, the expected value for the “No Pilot” alternative is \$115 MM and for the “Pilot” alternative it is \$210 MM.

### 8.3.8 Step 8: Determine the Value of Information

With both the expected utilities for the “No Pilot” and “Pilot” the value of information (VOI) can be calculated. The VOI is equal to the expected utility of the “Pilot” alternative minus the utility of the selected alternative for the “No Pilot” decision.

$$VOI = \sum_j \max[E(U_{WF|Pilot}), E(U_{EOR|Pilot})] = \sum_j [\max(U_{WF|Pilot}, U_{EOR|Pilot})P(E_j)]$$

**Equation 8-5**

It is up to the user to determine what the minimum the VOI should be to follow through with the pilot decision. The VOI ranges from zero to positive infinity, with zero meaning the pilot provides no benefit. It is beneficial to run a value of perfect information (VPI) analysis because the VPI represents the most value a pilot could provide. Example A is a VPI analysis.

For Example A, the expected value of the “No Pilot” alternative is \$115 MM and for the “Pilot” alternative it is \$210 MM. Therefore, the VPI is \$95 MM, which suggests the pilot offers information that is at most expected to be worth \$95 MM. If this value is above the original threshold established for a pilot’s value, then more detailed analyses where existing information and imperfect pilot information is assumed. Otherwise, the decision is to not perform a pilot.

#### **8.4 Updating the Non-Informative Prior, Example B**

After step three, another step may be added to create a more realistic analysis. The decision maker may decide to add any information that may be readily available. For example, if the user has a good understanding of a limited range for  $P_o$  or some idea about the  $V_P$  for the field based on water flood history, then this information may be represented with a likelihood function and applied through Bayes’ theorem.

For Example B, it is assumed that the decision maker has some understanding about the parameters. Table 8-7 is a summary of the assumed probability distribution based on previous experience. Figure 8-14 is a plot of the likelihood function assumed from prior experiences. Simple functions are used to illustrate how limiting the ranges

for the parameters influence the prior probability distributions. Through Bayes' theorem, the non-informative distribution is updated with the information from the assumed distributions, creating the updated prior distribution shown in Figure 8-15.

**Table 8-7 Example Likelihood Functions for Each Parameter Based on Existing Information**

$\Delta S_o$	Likelihood	$\log(P_o)$	Likelihood	$\log(V_p)$	Likelihood
		$\log(\$/STB)$		$\log(RB)$	
0.04	1.0	0.4	0.0	6.5	0.00
0.11	1.0	1.2	1.0	7.5	1.0
0.18	1.0	2.0	1.0	8.5	1.0
0.25	0.00	2.8	0.0	9.5	1.0
0.32	0.00	3.6	0.0	10.5	0.00

**Figure 8-14 Likelihood Function for the Information Based on Experience**

**Figure 8-15 Probability Distribution of the Update Prior Distribution Based on Information from Experience**

The new information acts like a filter, eliminating several events from consideration. Of the remaining events, the ones with the most weight are  $\log(P_o) = 2$   $\log(\$/STB)$ ,  $\log(V_p) = 8.3$  and  $9.4$   $\log(RB)$ , and  $\Delta S_o = 0.18$ . The expected values of the decision are summarized in Table 8-8.

**Table 8-8 Comparison of VPI Analyses for Examples A and B**

	"No Pilot" Alternative			"Pilot" Alternative	VPI (\$MM)
	$U_{EOR}$ (\$MM)	$U_{WF}$ (\$MM)	Selected (\$MM)	Expected Value (\$MM)	
Example A	-959	115	115	210	95
Example B	-2182	134	134	165	31

The new information has removed some of the uncertainty that existed with the original prior distribution and therefore the adjusted prior distribution is less sensitive to perfect information from the pilot. Example B demonstrates how a pilot, or any source of new information, is typically most valuable when no other information exists.

For Example B, the likelihood function that adjusts the non-informative prior is designed to remove events that are known to be impossible. Arbitrarily filtering events can lead to unintended bias in the decision. Therefore, a reasonable and rational approach that accounts for existing information from case histories (Chapter 4) and any existing information about the field is needed for creating consistent and unbiased likelihood functions.

### **8.5 Applying Monte Carlo Simulation to the Decision Analysis**

To perform a complete decision analysis, a decision maker has to evaluate many combinations of events and their simulations. A thorough analysis requires many simulations and lots of computation time. Monte Carlo is recommended to be used in the decision analyses because there are a large number of simulations that have to be performed, in particular with the preposterior analyses.

The simple example used for this chapter has three parameters with five events each. Each posterior analysis therefore has 125 event combinations. A complete posterior decision analysis would involve analyzing 25 potential pilot results. Each pilot result involves 125 event combinations that are also analyzed. All together, the posterior decision analysis requires 3125 events to be analyzed. A spreadsheet can handle the

computations for such an analysis; however, if a more thorough analysis is required, one with 50 events per each parameter, then there would be 2500 pilot events each with 125,000 events for each posterior decision. That leads to 312,500,000 simulated events for all of the posterior decisions. This full enumeration involves a staggering amount of simulations with SEORM and calculations for a spreadsheet. The run time for calculations becomes prohibitively long. Monte Carlo simulation provides considerable assistance in reducing the computation time without sacrificing much on accuracy.

To apply Monte Carlo to the decision analysis, first the prior and the preposterior probability distributions need to be determined. It is from these distributions that random samples of events for the input parameters are selected. With the prior distribution the expected value of the prior decision can be approximated. The preposterior distribution is calculated from probability of information for each possible pilot realization, and with it pilot realizations are randomly selected. For each pilot realization a posterior distribution is calculated from the prior probability distribution and the pilot's likelihood function. Again, random samples are selected from the posterior decision distributions and used to approximate the expected value of the posterior decision.

Programs were developed in Excel<sup>®</sup> that handle the calculations for the decision making process and can either perform a rigorous analysis that goes through every possible combination of events or a Monte Carlo simulation based analysis.

### 8.5.1 Monte Carlo Simulation Example

The following is an example of Monte Carlo being applied to the prior decision for the example decision discussed in this chapter. The expected utilities for the complete analysis, which takes into account all 125 events, are shown in Table 8-9. The table also shows the results from Monte Carlo simulations of various sizes. As the number of simulations increases, the accuracy of the results increases. It appears good accuracy requires about 1000 simulations, and therefore for this example Monte Carlo does not provide an advantage.

**Table 8-9 Comparison of Monte Carlo Results for Calculating the Utility of Prior Decision for a Simple Example**

		Expected Utilities (\$MM)	
		UEOR	UWF
Complete (125 Simulations)		-959	115
# of Simulations	10	-645	100
	100	-1025	113
	1000	-962	116
	10,000	-958	115

Results from a more thorough analysis are presented as well. This analysis has three parameters divided into 50 intervals and therefore required 125,000 simulations for an accurate result. Table 8-10 shows the results of the complete analysis as well as from Monte Carlo simulations. Again the accuracy improves with more simulations, with a good result occurring with about 1000 simulations. In this case, this is only a fraction of what is necessary for a complete enumeration. Therefore, considerable time can be saved without a significant loss in accuracy.

**Table 8-10 Comparison of Monte Carlo Results for Calculating the Utility of Prior Decision for a Complex Example**

		Expected Utilities (\$MM)	
		UEOR	UWF
Complete (125,000 Simulations)		-391	175
# of Simulations	100	-315	152
	1000	-370	182
	10,000	-395	174
	50,000	-395	174

Monte Carlo could also be used to assist with the preposterior decision. For the simpler problem with only five intervals, only 3125 simulations are necessary for a complete enumeration. As shown in Table 8-11, it once again appears that running a full analysis instead of Monte Carlo is preferred because a relatively few number of simulations are required. The numbers within parentheses in the table refers to the number of simulations for both the prior and posterior decisions. However, the Monte Carlo simulator does produce a reasonably accurate answer if the proper number of simulations is applied for both the prior and posterior decisions.

**Table 8-11 Comparison of Monte Carlo Results for Calculating the Utility of Preposterior Decision for a Simple Example**

		Expected Utilities (\$MM)	
		"No Go"	"Go"
Complete (3125 Simulations)		115	210
# of Simulations	10,000 (1000/10)	115	180
	25,000 (1000/25)	116	220
	50,000 (1000/50)	114	205
	100,000 (1000/100)	115	213
	1,000,000 (1000/1000)	115	212

For more thorough preposterior analyses, Monte Carlo simulation must be used because the computing becomes prohibitively long. The calculation time becomes more

extensive because of the calculation time associated with the simulations and distributions.

## **8.6 Summary**

Decision making involves several steps and components. The first step is to set up the decision in the form of a decision framework so that all of the information and how it is interrelated can be easily seen. The decision analysis for this thesis project involves several other decisions before the final one of “Go” versus “No Go” for a pilot. The next step is to establish non-informative prior probabilities so that a starting point can be set for the probability distribution of all of the events. The non-informative prior may then be updated with any existing data with Bayes’ theorem. A prior decision is first completed the utility of the selected alternative is the utility of the “No Go” alternative for the preposterior decision.

The posterior distributions are then established based on potential pilot outcomes. Each posterior decision is evaluated. The utility of the “Go” alternative for the preposterior decision is based on the preferred utilities for each posterior decision and the probabilities for each pilot realization.

Each decision requires considerable numeration because the events are supposed to be from a continuous set. Many simulations can create staggeringly long simulation times. Therefore, Monte Carlo simulation is being used to limit the number of simulations and computation time, without sacrificing accuracy.

Examples A and B presented in the chapter, demonstrate how the value of information from a pilot is sensitive to the available information prior to the decision. With more information applied early on in the decision analysis, the less valuable the pilot information becomes in these examples. A rational and reasonable methodology for determining likelihood functions to update existing probability distributions that includes information from case histories and field specific information from primary and secondary production data would be valuable.

## **CHAPTER 9: CONCLUSIONS AND FUTURE WORK**

### **9.1 Review of the Research**

This study was focused on developing decision support for enhanced oil recovery (EOR) projects. To perform a decision analysis, there needed to be a way to determine the utility or monetary outcome of an EOR project based on potential reservoir characteristics. Therefore, the first step was to create a simple model that can handle forecasting oil production for three different forms of isothermal EOR methods, surfactant-polymer (SP), alkali-surfactant-polymer (ASP), and CO<sub>2</sub> flooding. This model is known as the simplified enhanced oil recovery method (SEORM). It was evaluated with field data to ensure that it is able to create accurate oil production history curves based on reservoir properties. An economic model was also created as means to determine the economic value of a project. A sensitivity analysis was then performed to better understand how the parameters of SEORM and the economic model influence the value of a project. The decision tree and the decision making process were then set up and explained. Finally, a simple example was used to demonstrate the decision making process for determining the value of information of a pilot. The process discussed in this study was designed to avoid bias, inconsistency, and other issues common with establishing probability distributions for events with uncertainty.

### **9.2 Conclusions**

There are essentially two sets of conclusions that can be drawn from this research. The first set involves SEORM and the other set is from the decision analysis.

### 9.2.1 Conclusions about the Simplified Enhanced Oil Recovery Method

SEORM is designed to be a simple in that it only requires a few physically meaningful parameters to characterize an oil production history curve. The method is simple with only four fitting parameters for SP, ASP, and CO<sub>2</sub> floods. Assuming an incomplete fractional flow curve, for SP and ASP flood the change in oil saturation ( $\Delta S_o$ ), two Koval factors ( $K_1$  and  $K_2$ ), and the specific shock velocity of the oil bank ( $v_{oB}$ ) are assumed. The Koval factors and  $v_{oB}$  capture the heterogeneity and mobility issues. For CO<sub>2</sub> floods,  $\Delta S_o$ ,  $K_1$ ,  $v_{oB}$ , and total pore volume of the reservoir ( $V_P$ ) must be assumed for the fit. If the fractional flow curve is known, then  $v_{oB}$  is not assumed, which reduces the number of fitting parameters to three.

Based on the evaluation with existing field data, the method appears to work very well in creating oil production history curves that fit pilot and field data. SEORM appears to be capable of creating most potential oil production history curves that could occur. The method is based on fractional flow theory, and the strong fits further suggest that fractional flow theory can be a good indicator of a field's performance.

Several generic correlations between the field properties and performance are noted based on the evaluation fittings. First it is observed that larger scale fields tend to perform less efficiently than smaller fields. This observation is based on the fact there is a general tendency for large fields to have lower change in oil saturation, higher Koval factor values, and higher specific shock velocities than smaller fields.

Another observation is that SP and ASP floods behave quite differently from CO<sub>2</sub> floods. SP and ASP floods tend to have  $K_2$  values that vary between  $K_1$  and  $K_{2,max}$ , which implies that the oil bank typically arrives at the producer before the injected chemical bank. For CO<sub>2</sub> floods, the best fits are with  $K_2$  equal to  $K_{2,max}$ , which implies the solvent and oil banks arrive at the producers the same time. SP and ASP floods also have better sweep and shorter flood lives in terms of dimensionless time than CO<sub>2</sub> floods because SP and ASP floods have lower Koval factors and specific shock velocities than CO<sub>2</sub> floods. These trends are consistent with field experiences.

The sensitivity analysis of SEORM and the economic model for the three flood types shows that the most influential parameters are  $\Delta S_o$ , price of oil ( $P_o$ ), and  $V_P$ . These variables are most important because they directly influence profit potential for a project. The next most important parameters deal with the injected volume and concentration of the injected chemicals or solvent because the cost of the injected fluids is the most significant expense.

### **9.2.2 Conclusions about the Decision Making Process**

The decision analysis for this thesis project involves several decisions including one between “Go” and “No Go” for a pilot and others between EOR and continued water flooding. An important early step for the decision analysis is to set up the non-informative prior probabilities as a starting point for the probability distribution of all of the events. Following the principle of insufficient reason (PIR) and assuming all input values are equally likely with arbitrarily assumed ranges of values for the events is not an

adequate approach because it creates inconsistent probability distribution between users. The decision-based method (DBM) addresses the inadequacies because it applies (PIR) to the output of the decision and it is recommended decision analysis.

Some non-informative prior distributions for the input parameters change in oil saturation ( $\Delta S_o$ ), oil price ( $P_o$ ), and total pore volumes ( $V_p$ ) are created with DBM. The method demonstrates that there are positive and negative infinite limits for  $P_o$  and  $V_p$ . It also shows correlations between the parameters, suggesting that the inputs are not independent when it comes to altering the final decision. For example, if  $P_o$  is very high, then low  $\Delta S_o$  values can still allow for EOR to be preferred over continued water flooding.

The simple example in the thesis demonstrates that the value of information for a pilot diminishes as more information is applied early to the decision. Therefore, the pilot is most valuable under conditions where there is little experience or understanding about a reservoir's properties.

### **9.3 Recommendations for Future Work**

It is recommended that SEORM be evaluated with more field data, especially with ASP floods. More evaluations can provide a more representative sample set for determining representative ranges of SEORM's input parameters. The extra evaluations can improve confidence in the method's accuracy for creating representative oil production curves. More evaluations may also assist with determining potential trends between SEORM's inputs and measurable reservoir characteristics. If trends can be

developed then basic means for approximating the parameter values can be used for more accurate and reasonable forecasting.

Another recommendation is to adjust the evaluations of SEORM for SP and ASP floods to allow  $V_P$  to be an adjustable parameter. Currently it is not recommended to allow  $V_P$  to be an adjustable parameter because several significantly different satisfactory fits can be created. If the evaluation process is adjusted so that the number of fits is limited then potentially more accurate and more representative fits can be created.

Another recommendation is for the decision analyses to take into account more variables with more intervals for the parameters are performed. This study focused on establishing the method of decision making so that consistent probability distributions can be created. More analyses are required to study how the parameters and different conditions alter the decision.

Finally, it is recommended that reasonable and rational approach be created for determining likelihood functions that represent information. There is currently no process for creating likelihood functions based on existing information. Typically, the distributions come from judgment based on past experiences; however, this can lead to unintended bias and is a questionable approach. A process is needed so the distributions can be created in consistent manner.

## **APPENDIX A: EVALUATION FITS**

### **A.1 Fitted Pilot Scale Surfactant-Polymer Floods**

The following is the full set of pilot scale SP flood project that were fitted with SEORM along with the inputs used for the fits. All of the tables have colored cells. The light blue cells are values fitted with SEORM. The light green cells are values provided in the literature. The light purple cells are the values fitted for the fractional flow curve. All other cells are calculated values based on the other inputs.

Several plots are provided for every fit, including ones for oil cut, oil saturation, oil production rate, oil recovery, and the fitted fractional flow curve.

## A.2 Fitted Field Scale Surfactant-Polymer Floods

The following is the full set of field scale SP flood project that were fitted with SEORM along with the inputs used for the fits. The tables follow the same color scheme mentioned earlier. Several plots are provided for every fit, including ones for oil cut, oil saturation, oil production rate, oil recovery, and the fitted fractional flow curve.

### A.2.1 M-1 2.5 Acre Field

Table A-11 Summary of Inputs for M-1 2.5 Acre Field

Oil Saturations		Fractional Flow Inputs		
$S_{oi}$	0.75	$k_{rw}^o$	0.15	
$S_{oR}$	0.40	$k_{ro}^o$	0.80	
$S_{or}$	0.32	N	3.0	
$S_{oB}$	0.45	M	2.0	
$S_{oF}$	0.31	$\mu_o$	7.0	cp
$\Delta S_o$	0.09	$\mu_w$	1.0	cp
Oil Cuts		$\mu_c$ (Inj. Chem.)	25.0	cp
$f_{oi}$	0.05	Reservoir Properties		
$f_{oB}$	0.20	$V_p$	9E+06	RB
$f_{oF}$	0.00	OOIP	7E+06	STB
Flood Behavior		$B_o$	1.00	RB/STB
$K_1$	1.62	Well Spacing	2.5	acres
$K_2$	2.42	Field Size	200	acres
$v_{oB}$	3.10	Other Inputs		
$v_C$	1.45	$Z_{sur}$	10	% conc.
$K_f$	0.43	$Z_{poly}$	750	ppm
Flood Injection Inputs				
Fluid	Surfactant	Polymer	Water	
$q_i$	1470	4360	3800	STB/day
$q_p$	1470	4360	3800	STB/day

## A.4 Fitted Pilot and Field Scale Carbon Dioxide Floods

The following is the full set of pilot and field scale CO<sub>2</sub> flood projects that were fitted with SEORM along with the inputs used for the fits. The tables follow the same color scheme mentioned earlier. Several plots are provided for every fit, including ones for oil cut, oil saturation, oil production rate, oil recovery, and the fractional flow curve.

### A.4.1 Lost Soldier Field

Table A-24 Summary of Inputs for Lost Soldier Field

Oil Saturations		Fractional Flow Inputs		
S <sub>oi</sub>	0.90	k <sub>rw</sub> <sup>o</sup>	0.15	
S <sub>or</sub>	0.50	k <sub>ro</sub> <sup>o</sup>	0.90	
S <sub>or</sub>	0.48	n	4.0	
S <sub>oB</sub>	0.59	m	1.5	
S <sub>oF</sub>	0.20	μ <sub>o</sub>	1.4	cp
ΔS <sub>o</sub>	0.30	μ <sub>w</sub>	1.0	cp
Oil Cuts		μ <sub>c</sub> (Inj. Chem.)	0.1	cp
f <sub>oi</sub>	0.04	Reservoir Properties		
f <sub>oB</sub>	0.65	Provided V <sub>p</sub>	3.0E+08	RB
f <sub>oF</sub>	0.00	Fitted V <sub>p</sub>	1.3E+08	RB
Flood Behavior		OOIP	1E+08	STB
K <sub>1</sub>	5.40	B <sub>o</sub>	1.12	RB/STB

## **APPENDIX B: RELATIONSHIPS BETWEEN RESERVOIR CHARACTERISTICS AND FITTING PARAMETERS**

### **B.1 Introduction**

As a means to help put in perspective what the fitting parameters for the simplified enhanced oil recovery method (SEORM) mean, attempts were made to determine if relationships exist between the parameters and various reservoir characteristics. From a review of the fits, it appears that no trends seem to exist. This does not mean that the parameters do not capture certain aspects of a reservoir's properties, but rather it suggests that the parameters may capture combinations of the characteristics. Going into considerable detail about determining if relationships exist is out of the scope of this research project. Coming up with basic ranges for the fitted parameters is enough to allow one to perform a decision analysis that can simulate any potential outcome. It may be interesting to see if meaningful relationships can be developed as SEORM is fitted to more data.

## **APPENDIX C: SENSITIVITY ANALYSIS PLOTS**

### **C.1 Introduction**

The following is a collection of all of the plots created for the sensitivity analysis. These plots are discussed in more detail in Chapter 6.

### **C.2 Sensitivity Analysis Plots for Surfactant-Polymer Floods**

The following are all of the plots produced for the sensitivity analysis of all of the parameters associated with surfactant-polymer floods.

#### **C.2.1 Sensitivity Plots for the Parameters of the Simplified Enhanced Oil Recovery**

##### **Method**

These plots include analyses of the following parameters: change in oil saturation, total pore volumes, heterogeneity factors, and the specific shock velocity of the oil bank.

### C.2.1.1 Change in Oil Saturation

Figure C-1 Plot of Oil Cut against Dimensionless Time for Varying  $\Delta S_o$  for SP Floods

Figure C-2 Plot of Oil Saturation against Dimensionless Time for Varying  $\Delta S_o$  for SP Floods

Figure C-3 Plot of Oil Recovery against Time for Varying  $\Delta S_0$  for SP Floods

Figure C-4 Plot of CDCF against Time for Varying  $\Delta S_0$  for SP Floods

### C.2.1.2 Total Pore Volumes

Figure C-5 Plot of Oil Cut against Time for a Varying  $V_p$  for SP Floods

Figure C-6 Plot of Oil Saturation against Time for a Varying  $V_p$

Figure C-7 Plot of Oil Recovery against Time for a Varying  $V_p$  for SP Floods

Figure C-8 Plot of CDCF against Time for a Varying  $V_p$  for SP Floods

### C.2.1.3 Heterogeneity Factors

Figure C-9 Plot of Oil Cut against Dimensionless Time for a Varying  $K_1$  for SP Floods

Figure C-10 Plot of Oil Saturation against Dimensionless Time for a Varying  $K_1$  for SP Floods

Figure C-11 Plot of Oil Recovery against Time for a Varying  $K_1$  for SP Floods

Figure C-12 Plot of CDCF against Time for a Varying  $K_1$  for SP Floods

Figure C-13 Plot of Oil Cut against Dimensionless Time for a Varying  $K_f$  for SP Floods

Figure C-14 Plot of CDCF against Time for a Varying  $K_f$  for SP Floods

#### C.2.1.4 Specific Shock Velocity of Oil Bank

Figure C-15 Plot of Oil Cut against Dimensionless Time for a Varying  $v_{oB}$  for SP Floods

Figure C-16 Plot of CDCF against Time for a Varying  $v_{oB}$  for SP Floods

### C.2.2 Sensitivity Plots of the Design Parameters

These plots include analyses of the following design parameters: well spacing, injection rate, production rate, pore volumes for the injected chemicals, and concentrations for the chemicals.

#### C.2.2.1 Well Spacing

Figure C-17 Plot of Oil Recovery against Time for a Varying WS for SP Floods

Figure C-18 Plot of CDCF against Time for Varying WS for SP Floods

#### C.2.2.2 Injection Rate

Figure C-19 Plot of Oil Cut against Time for a Varying  $q_i$  for SP Floods

Figure C-20 Plot of CDCF against Time for a Varying  $q_i$  for SP Floods

### C.2.2.3 Production Rate

Figure C-21 Plot of CDCF against Time for Varying  $q_p$  for SP Floods

#### C.2.2.4 Surfactant-Polymer and Polymer Slug Sizes

Figure C-22 Plot of CDCF against Time for Varying  $V_{Chem}$  for SP Floods

Figure C-23 Plot of CDCF against Time for Varying  $V_{Poly}$  for SP Floods

### C.2.2.5 Concentrations of Surfactant and Polymer

Figure C-24 Plot of CDCF against Time for Varying  $Z_{Sur}$  for SP Floods

Figure C-25 Plot of CDCF against Time for Varying  $Z_{Poly}$  SP Floods

### C.2.3 Sensitivity Plots for Economic Parameters

The following plots are for the following economic parameter: price of oil, escalation factor, price of surfactant, price of polymer, cost of injection, cost of treatment, cost of water disposal, upfront costs, maintenance costs, royalties, ad-valorem tax, severance tax, inflation, and discount rate.

#### C.2.3.1 Price of Oil and Escalation Factor for the Price of Oil

Figure C-26 Plot of CDCF against Time for Varying  $P_o$  for SP Floods

Figure C-27 Plot of CDCF against Time for Varying  $R_E$  for SP Floods

### C.2.3.2 Price of Surfactant and Polymer

Figure C-28 Plot of CDCF against Time for Varying  $C_{Sur}$  for SP Floods

Figure C-29 Plot of CDCF against Time for Varying  $C_{Poly}$  for SP Floods

### C.2.3.3 Costs of Injection, Treatment, Water Disposal

Figure C-30 Plot of CDCF against Time for Varying  $C_q$  for SP Floods

Figure C-31 Plot of CDCF against Time for Varying  $C_T$  for SP Floods

Figure C-32 Plot of CDCF against Time for Varying  $C_{WD}$  for SP Floods

### C.2.3.4 Upfront and Maintenance Costs

Figure C-33 Plot of CDCF against Time for a Varying  $C_1$  for SP Floods

Figure C-34 Plot of CDCF against Time for a Varying  $C_M$  for SP Floods

### C.2.3.5 Royalty, Ad-Valorem Tax, Severance Tax

Figure C-35 Plot of CDCF against Time for a Varying  $T_R$  for SP Floods

Figure C-36 Plot of CDCF against Time for a Varying  $T_V$  for SP Floods

Figure C-37 Plot of CDCF against Time for a Varying  $T_s$  for SP Floods

#### C.2.3.6 Inflation and Discount Rate

Figure C-38 Plot of CDCF against Time for a Varying  $i$  for SP Floods

Figure C-39 Plot of CDCF against Time for a Varying  $d$  for SP Floods

### C.3 Sensitivity Analysis Plots for Alkaline-Surfactant-Polymer Floods

The following are all of the plots produced for the sensitivity analysis of all of the parameters associated with alkali-surfactant-polymer floods.

#### C.3.1 Sensitivity Analysis Plots of the Parameters for the Simplified Enhanced Oil

##### Recovery Method

These plots include analyses of the following parameters: change in oil saturation, total pore volumes, heterogeneity factors, and the specific shock velocity of the oil bank.

### C.3.1.1 Change in Oil Saturation

Figure C-40 Plot of Oil Cut against Dimensionless Time for Varying  $\Delta S_o$  for ASP Floods

Figure C-41 Plot of Oil Saturation against Dimensionless Time for Varying  $\Delta S_o$  for ASP Floods

Figure C-42 Plot of Oil Recovery against Time for Varying  $\Delta S_0$  for ASP Floods

Figure C-43 Plot of CDCF against Time for Varying  $\Delta S_0$  for ASP Floods

### C.3.1.2 Total Pore Volumes

Figure C-44 Plot of Oil Cut against Time for a Varying  $V_p$  for ASP Floods

## C.4 Sensitivity Analysis Plots for CO<sub>2</sub> Floods

The following are all of the plots produced for the sensitivity analysis of all of the parameters associated with CO<sub>2</sub> floods.

### C.4.1 Sensitivity Analysis Plots of the Parameters for the Simplified Enhanced Oil

#### Recovery Method

These plots include analyses of the following parameters: change in oil saturation, total pore volumes, heterogeneity factors, and the specific shock velocity of the oil bank.

#### C.4.1.1 Change in Oil Saturation

Figure C-82 Plot of Oil Cut against Dimensionless Time for Varying  $\Delta S_o$  for CO<sub>2</sub> Floods

Figure C-83 Plot of Oil Saturation against Dimensionless Time for Varying  $\Delta S_o$  for CO<sub>2</sub> Floods

Figure C-84 Plot of Oil Recovery against Time for Varying  $\Delta S_o$  for CO<sub>2</sub> Floods

Figure C-85 Plot of CDCF against Time for Varying  $\Delta S_0$  for CO<sub>2</sub> Floods

#### C.4.1.2 Total Pore Volumes

Figure C-86 Plot of Oil Cut against Time for a Varying  $V_p$  for CO<sub>2</sub> Floods

**Figure C-87 Plot of Oil Saturation against Time for a Varying  $V_p$  for  $\text{CO}_2$  Floods**

**Figure C-88 Plot of Oil Recovery against Time for a Varying  $V_p$  for  $\text{CO}_2$  Floods**

Figure C-89 Plot of CDCF against Time for a Varying  $V_p$  for  $\text{CO}_2$  Floods

#### C.4.1.3 Heterogeneity Factors

Figure C-90 Plot of Oil Cut against Dimensionless Time for a Varying  $K_1$  for  $\text{CO}_2$  Floods

Figure C-91 Plot of Oil Saturation against Dimensionless Time for a Varying  $K_1$  for  $\text{CO}_2$  Floods

Figure C-92 Plot of Oil Recovery against Time for a Varying  $K_1$  for  $\text{CO}_2$  Floods

Figure C-93 Plot of CDCE against Time for a Varying  $K_1$  for CO<sub>2</sub> Floods

Figure C-94 Plot of Oil Cut against Dimensionless Time for a Varying  $K_r$  for CO<sub>2</sub> Floods

Figure C-95 Plot of CDCF against Time for a Varying  $K_f$  for  $\text{CO}_2$  Floods

#### C.4.1.4 Specific Shock Velocity of Oil Bank

Figure C-96 Plot of Oil Cut against Dimensionless Time for a Varying  $v_{ob}$  for  $\text{CO}_2$  Floods

Figure C-97 Plot of CD CF against Time for a Varying  $v_{oB}$  for CO<sub>2</sub> Floods

#### C.4.2 Sensitivity Plots of the Design Parameters

These plots include analyses of the following design parameters: well spacing, injection rate, production rate, pore volumes for the injected chemicals, and water to gas (WAG) ratio.

### C.4.2.1 Well Spacing

Figure C-98 Plot of Oil Recovery against Time for a Varying WS for CO<sub>2</sub> Floods

Figure C-99 Plot of CDCF against Time for Varying WS for CO<sub>2</sub> Floods

### C.4.2.2 Injection Rate

Figure C-100 Plot of Oil Cut against Time for a Varying  $q_i$  for CO<sub>2</sub> Floods

Figure C-101 Plot of CDCF against Time for a Varying  $q_i$  for CO<sub>2</sub> Floods

### C.4.2.3 Production Rate

Figure C-102 Plot of CDCF against Time for Varying  $q_p$  for CO<sub>2</sub> Floods

### C.4.2.4 CO<sub>2</sub> Slug Sizes

Figure C-103 Plot of CDCF against Time for Varying  $V_{CO_2}$  for CO<sub>2</sub> Floods

### C.4.2.5 WAG Ratio

Figure C-104 Plot of Oil Cut against Dimensionless Time for Varying  $Z_{CO_2}$  (WAG) for  $CO_2$  Floods

Figure C-105 Plot of CDCF against Time for Varying  $Z_{CO_2}$  (WAG) for  $CO_2$  Floods

### C.4.3 Sensitivity Plots for Economic Parameters

The following plots are for the following economic parameter: price of oil, escalation factor, price of CO<sub>2</sub>, cost of injection, cost of treatment, cost of water disposal, upfront costs, maintenance costs, royalties, ad-valorem tax, severance tax, inflation, and discount rate.

#### C.4.3.1 Price of Oil and Escalation Factor for the Price of Oil

Figure C-106 Plot of CDCF against Time for Varying  $P_o$  for CO<sub>2</sub> Floods

Figure C-107 Plot of CDCF against Time for Varying  $R_E$  for CO<sub>2</sub> Floods

#### C.4.3.2 Price of CO<sub>2</sub>

Figure C-108 Plot of CDCF against Time for Varying  $C_{CO_2}$  for CO<sub>2</sub> Floods

### C.4.3.3 Costs of Injection, Treatment, and Water Disposal, and Softening

Figure C-109 Plot of CDCF against Time for Varying  $C_q$  for CO<sub>2</sub> Floods

Figure C-110 Plot of CDCF against Time for Varying  $C_T$  for CO<sub>2</sub> Floods

Figure C-111 Plot of CDCF against Time for Varying  $C_{WD}$  for  $CO_2$  Floods

#### C.4.3.4 Upfront and Maintenance Costs

Figure C-112 Plot of CDCF against Time for a Varying  $C_1$  for  $CO_2$  Floods

Figure C-113 Plot of CDCF against Time for a Varying  $C_M$  for CO<sub>2</sub> Floods

#### C.4.3.5 Royalty, Ad-Valorem Tax, Severance Tax

Figure C-114 Plot of CDCF against Time for a Varying  $T_R$  for CO<sub>2</sub> Floods

Figure C-115 Plot of CDCF against Time for a Varying  $T_v$  for CO<sub>2</sub> Floods

### C.4.3.6 Inflation and Discount Rate

Figure C-117 Plot of CDCF against Time for a Varying i for CO<sub>2</sub> Floods

Figure C-118 Plot of CDCF against Time for a Varying d for CO<sub>2</sub> Floods

## **APPENDIX D: EXTRA PLOTS FOR THE DEMONSTRATION OF THE DECISION BASED METHOD**

### **D.1 Introduction**

The following is a collection of all of the plots created for the example of the decision based method (DBM) in Chapter 8. The significance of these plots is discussed in Chapter 8 and is briefly reviewed throughout this appendix. The example for demonstrating DBM is based on three parameters, change in oil saturation ( $\Delta S_o$ ), total pore volumes ( $V_P$ ), and price of oil ( $P_o$ ), and two alternatives, enhanced oil recovery (EOR) and water flooding (WF).

### **D.2 Plots of Analyses with a Single Parameter**

The following are plots of the probability density functions (PDF) and cumulative density functions (CDF) created with DBM when only one parameter is considered.

#### **D.2.1 Plots of Probability Density Functions against Utilities for Single Parameters**

Figure D-1 and Figure D-2 are plots that show that the PDF reflects changes in the utility values for EOR and WF. These help to demonstrate how the PDFs created with DBM are sensitive to changes in decision and to utility set outcomes.

Figure D-1 Plot of the PDF against the Utilities for  $\Delta S_0$

Figure D-2 Plot of the PDF against the Utilities for  $P_0$

### D.2.2 Plots Demonstrating Sensitivity to Resolution for a Single Parameter

The following plots demonstrate how sensitive DBM is to the number of intervals used for each parameter in the analysis. The higher resolution allows for more accuracy in determining at which points the decision and the utility set outcomes changes.

(a) PDF

(b) CDF

Figure D-3 Plots of the PDF and CDF for  $\Delta S_0$  with Varying Resolution

(a) PDF

(b) CDF

Figure D-4 Plots of the PDF and CDF for  $P_0$  with Varying Resolution

### D.3 Two Parameter Analyses

The following are plots of the joint PDFs and CDFs for analyses that consider two varying parameters. These plots help show how different parameter combinations produce different probability distributions because the kinds of outcomes vary considerably between the different combinations.

Figure D-5 Plots of the Joint PDF and CDF for the Combination of  $\Delta S_0$  and  $P_0$

(a) Joint PDF

(b) Joint CDF

Figure D-6 Plots of the Joint PDF and CDF for the Combination of  $V_p$  and  $P_o$

(a) Joint PDF

(b) Joint CDF

Figure D-7 Plots of the Joint PDF and CDF for the Combination of  $\Delta S_o$  and  $V_p$

#### D.4 Three Parameter Analyses

The following plots illustrate how the probability distributions change when all three parameters are considered. Analyses were also performed to demonstrate how sensitive DBM is to the selected ranges for each parameter. The complete range attempts to look at all possible values. The plots created with this range are used for comparisons between other analyses. The selected range is based on a narrow range of value that encompasses all possible outcome sets, and therefore neglects meaningless events. The narrowed range is a narrower set of ranges that are arbitrarily selected. Table D-1 is a summary of the different ranges used for the sensitivity analysis.

**Table D-1 Summary of the Ranges used in the Sensitivity Analysis for DBM**

Parameter	Complete Range		Selected Range		Narrowed Range	
	Low	High	Low	High	Low	High
$\Delta S_o$	0.01	0.35	0.01	0.35	0.05	0.25
$\log(P_o), \log(\$ / \text{STB})$	0	8	0	4	1	3
$\log(V_p), \log(\text{RB})$	0	11	6	11	7	9

There is minimal difference between distributions based on the complete and selected ranges because the outcomes and the utility sets that influence the decision are the same between the two sets of ranges. However, there is considerable difference between the narrowed range and the other two because several important outcomes have been eliminated, which alters the probability distributions.

#### D.4.1 Three Parameter Analyses with Complete Ranges

Figure D-8 Plots of the Joint PDF and CDF for  $\Delta S_o$  and  $P_o$  based on the Combination of  $\Delta S_o$ ,  $P_o$ , and  $V_p$  with Complete Ranges

Figure D-9 Plots of the Joint PDF and CDF for  $V_p$  and  $P_o$  based on the Combination of  $\Delta S_o$ ,  $P_o$ , and  $V_p$  with Complete Ranges

Figure D-10 Plots of the Joint PDF and CDF for  $\Delta S_0$  and  $V_p$  based on the Combination of  $\Delta S_0$ ,  $P_o$ , and  $V_p$  with Complete Ranges

#### D.4.2 Three Parameter Analyses with Selected Ranges

Figure D-11 Plots of the Joint PDF and CDF for  $\Delta S_0$  and  $P_o$  based on the Combination of  $\Delta S_0$ ,  $P_o$ , and  $V_p$  with Selected Ranges

**Figure D-12 Plots of the Joint PDF and CDF for  $V_P$  and  $P_o$  based on the Combination of  $\Delta S_o$ ,  $P_o$ , and  $V_P$  with Selected Ranges**

**Figure D-13 Plots of the Joint PDF and CDF for  $\Delta S_o$  and  $V_P$  based on the Combination of  $\Delta S_o$ ,  $P_o$ , and  $V_P$  with Selected Ranges**

### D.4.3 Three Parameter Analyses with Narrowed Ranges

Figure D-14 Plots of the Joint PDF and CDF for  $\Delta S_0$  and  $P_0$  based on the Combination of  $\Delta S_0$ ,  $P_0$ , and  $V_p$  with Narrowed Ranges

Figure D-15 Plots of the Joint PDF and CDF for  $V_p$  and  $P_0$  based on the Combination of  $\Delta S_0$ ,  $P_0$ , and  $V_p$  with Narrowed Ranges

Figure D-16 Plots of the Joint PDF and CDF for  $\Delta S_0$  and  $V_p$  based on the Combination of  $\Delta S_0$ ,  $P_o$ , and  $V_p$  with Narrowed Ranges

#### D.4.4 Comparison of All Three Range Types

The following are plots of the marginal PDFs for the three parameters. These plots allow for an easy way to see how the ranges influence the distributions.

Figure D-17 Plots of the Marginal PDF for  $\Delta S_0$  based on the Combination of  $\Delta S_0$ ,  $P_o$ , and  $V_p$  with Various Ranges

Figure D-18 Plots of the Marginal PDF for  $P_o$  based on the Combination of  $\Delta S_o$ ,  $P_o$ , and  $V_p$  with Various Ranges

Figure D-19 Plots of the Marginal PDF for  $V_p$  based on the Combination of  $\Delta S_o$ ,  $P_o$ , and  $V_p$  with Various Ranges

## D.5 Monte Carlo Comparisons

The following are plots the results of a Monte Carlo simulation for DBM with the “selected” ranges. The Monte Carlo simulation is with 40,000 randomly selected points.

### D.5.1 Monte Carlo Comparisons for Joint PDFs and CDFs

Figure D-20 Plots of the Joint PDF and CDF from Monte Carlo Simulation for  $\Delta S_o$  and  $P_o$  based on the Combination of  $\Delta S_o$ ,  $P_o$ , and  $V_p$  with Selected Ranges

Figure D-21 Plots of the Joint PDF and CDF from Monte Carlo Simulation for  $V_p$  and  $P_o$  based on the Combination of  $\Delta S_o$ ,  $P_o$ , and  $V_p$  with Selected Ranges

Figure D-22 Plots of the Joint PDF and CDF from Monte Carlo Simulation for  $\Delta S_o$  and  $V_p$  based on the Combination of  $\Delta S_o$ ,  $P_o$ , and  $V_p$  with Selected Ranges

### D.5.2 Monte Carlo Comparisons for Marginal PDFs and CDFs

The comparison of the rigorous analysis and the Monte Carlo analysis is more easily seen with the marginal PDFs and CDFs.

**Figure D-23 Comparison of the Marginal PDFs and CDFs for the Rigorous and Monte Carlo Simulations for  $\Delta S_0$**

Figure D-24 Comparison of the Marginal PDFs and CDFs for the Rigorous and Monte Carlo Simulations for  $P_o$

Figure D-25 Comparison of the Marginal PDFs and CDFs for the Rigorous and Monte Carlo Simulations for  $V_p$

## **APPENDIX E: NOMENCLATURE**

### **E.1 Introduction**

The following is a summary of all of the abbreviated terms, parameters, and units used throughout the thesis.

### **E.2 Units**

Table E-1 is a list of abbreviated units used throughout the thesis.

**Table E-1 List of Abbreviated Units**

BOPD	Barrels of oil per day
BPD	Barrels per day
CF	Cubic feet
cp	Centipoises
lb	Pound
M	Thousand
MM	Million
RB	Reservoir barrel
STB	Stock-tank barrel
WAG	Water alternating gas ratio

### E.3 Abbreviations and Acronyms

Table E-2 is a list of abbreviations and acronyms used throughout the thesis.

**Table E-2 List of Abbreviations and Acronyms**

ASP	Alkali-surfactant-polymer
CDCF	Cumulative discounted cash flow
CDCFM	Cumulative discounted cash flow method
CDF	Cumulative distribution function
CFPM	Chemical flood predictive model
CO <sub>2</sub>	Carbon dioxide
COV	Coefficient of variation
DBM	Decision based method
EOR	Enhanced oil recovery
MNPV	Max net present value
NPV	Net present value
OOIP	Original oil at place (at time of discovery)
PDF	Probability density function
PIR	Principle of insufficient reason
PMF	Probability mass function
SEORM	Simplified enhanced oil recovery method
SP	Surfactant-polymer
VOI	Value of information
VPI	Value of perfect information
WF	Water flooding

## E.4 Parameters and Variables

Table E-3 is a list of the parameters associated with the simplified enhanced oil recovery method. More details can be found in Chapter 3.

**Table E-3 List of Parameters Associated with SEORM**

$S_{oF}$	Average oil saturation at the end of the EOR flood
$K_1$	The Koval factor for the flow between the mobilized oil and initial banks
$K_2$	The Koval factor for the flow between the injected and mobilized oil banks
$K_f$	Scale factor for determining $K_2$
$v_{oB}$	Specific shock velocity of mobilized oil bank
$V_p$	Total pore volume of reservoir
$\Delta S_o$	Change in oil saturation over life of EOR flood

Table E-4 is a list of the parameters associated with the design inputs for an enhanced oil recovery project. These parameters are typically controlled and determined by the designers of the flood. More details can be found in Chapter 3 and 5.

**Table E-4 List of Parameters Associated with Design Inputs for an EOR Project**

$q_i$	Injection rate (constant for entire flood)
$q_p$	Production rate (constant for entire flood)
$V_{Chem}$	Surfactant or alkali slug size (For SP and ASP floods)
$V_{CO_2}$	CO <sub>2</sub> slug size
$V_{Poly}$	Polymer slug size
WS	Well spacing
$Z_{CO_2}$	CO <sub>2</sub> WAG ratio
$Z_{Alk}$	Alkali agent concentration
$Z_{Poly}$	Polymer concentration
$Z_{Sur}$	Surfactant concentration (For SP and ASP floods)

Table E-5 is a list of the economic parameters used to develop economic values of projects. More information on the parameters can be found in Chapter 5.

**Table E-5 List of Economic Parameters**

$C_A$	Unit price of alkali
$C_{CO_2}$	Unit price of $CO_2$ price
$C_I$	Start up cost per new well
$C_M$	Maintenance cost per well
$C_P$	Polymer price
$C_q$	Fluid injection cost
$C_{Soft}$	Softening Cost
$C_{Sur}$	Unit price of surfactant
$C_T$	Oil treatment cost
$C_{WD}$	Water disposal cost
$d$	Real discount rate (without inflation)
$i$	Inflation
$P_O$	Price of oil
$R_E$	Escalation factor for the price of oil
$T_R$	Royalty
$T_S$	Severance tax
$T_V$	Ad-valorem tax

Table E-6 is a list of the variables that are used as part of the statistical analyses. More details about the variables can be found in Chapters 4, 6, and 7.

**Table E-6 List of Statistical Variables**

$A$	An alternative for a decision analysis
$E$	An event for a decision analysis
$I$	Information for a decision analysis
$R^2$	Coefficient of determination
$S$	Sensitivity index, used for the sensitivity analysis
$U$	Utility, the value associated with an outcome in a decision analysis
$\mu$	Mean
$\sigma$	Standard deviation

Table E-7 is a list of all other parameters and variables used in derivations and other mathematical explanations.

**Table E-7 List of Other Parameters and Variables used throughout the Thesis**

A	Cross-sectional area of a reservoir
b	Number of wells
$B_o$	Formation volume factor for oil
C	Channeling variable
D	Decline rate in oil production
d	Real discount rate (Inflation is not included)
E	Effective viscosity
$F_{disp}$	Fractional flow of the displacing fluid
$f_o$	Oil cut at producer
$F_{oB}$	Fractional flow of the oil bank
$f_{oB}$	Peak oil cut for mobilized oil bank
$F_{oF}$	Fractional flow of the chasing fluids
$f_{oF}$	Oil cut at the end of EOR flood, assumed to be zero
$f_{oI}$	Oil cut at start of EOR flood
FV	Future value
H	Heterogeneity factor
I	Information for a decision analysis
$J_{disp}$	Saturation velocity of the displacing fluid
K	Koval factor
$K_{disp}$	Koval factor for displacing fluid
$K_f$	Koval scale factor
$k_{ro}^o$	End point relative permeability of oil
$k_{rw}^o$	End point relative permeability of water
L	Distance between injector and producer
m	Corey type exponent for oil
$m_A$	Mass of injected alkali
$m_p$	Mass of injected polymer
$m_{Sur}$	Mass of injected surfactant
n	Corey type exponent for water
$N_C$	Capillary number

$N_p$	Cumulative produced oil
PV	Present value
$q$	Volumetric flow
$q_I$	Injection rate
$q_P$	Production rate
$q_{WF}$	Injection rate for water flooding
$S$	Relative saturation of the system
$S'_i$	Magnitude of influence of a parameter $i$
SA	Surface area of project, field size
$S_{disp}$	Saturation of the displacing fluid
$S_{oB}$	Oil saturation within the mobilized oil bank
$S_{oF}$	Average oil saturation at the end of the EOR flood
$S_{oI}$	Average oil saturation at the start of EOR flood
$S_{or}$	Average residual oil saturation at the end of water flooding
$S_{or}$	Residual oil saturation
$S_{wr}$	Residual water saturation
$t$	Time
$t_D$	Dimensionless time in terms of injected pore volume
$u_{disp}$	Interstitial velocity for the displacing fluid
$v$	Effective flow rate
$v_C$	The specific shock velocity of the injected chemical bank
$v_{disp}$	The specific shock velocity of the displacing fluid
$v_{oB}$	The specific shock velocity of the mobilized oil bank
$V_p$	Total pore volume of reservoir
$x$	Distance from injector
$x_D$	Relative distance between injector and producer
$\phi$	Porosity
$\mu_o$	Viscosity of oil
$\mu_w$	Viscosity of water
$\nu$	Viscosity ratio
$\sigma$	Surface tension

## **VITA**

Panos Andonyadis was born in Baltimore, Maryland. After he completed his high school studies at Oakton High School in Vienna, Virginia, he went to Virginia Tech where he earned a Bachelor of Engineering degree with high honors in May, 2008. During the summers between 2004 and 2008, he completed multiple internships with various civil engineering firms, including time with companies such as ECS and CDM. In the fall of 2008, he enrolled into the Graduate School at The University of Texas at Austin to earn a Master of Engineering in the field of Geotechnical Engineering.

Permanent Address: 3104 Ashburton Avenue

Herndon, Virginia 20171
